INDEX TO VOLUME II FOR 1934

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma, Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria, and Sugar; Light, Roentgen, Radium, X Rays; Status Lymphaticus and Thymus; Eye, Ophthalmia, and Vision; Pyelography and Urography; Lunacy and Mental Diseases; Sunlight and Ultra-violet; Bicycle and Cycle; Motor and Automobile; Association, Institution, and Society, etc. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Annotations," "Correspondence," "Leading Articles," "Reviews," etc. Original Articles are indicated by the letter (O). For Obituary Notices see under Names of Individuals.

A.

- ABDERHALDEN, Emil, elected a corresponding foreign member of the Vienna Academy of Sciences, 337
- Abdominal cyst. See Cyst
- Abdominal pregnancy. See Pregnancy
- ABERCROMBIE, R. H.: The swab in diphtheria diagnosis, 375
- Aberdeen. See Scotland
- ABERLE, S. B. D.: Vitamin A and nerve lesions, 1053
- Abortion, contagious, discussion on, 483
- Abortion, contagious, and undulant fever in Northumberland (A. L. Messer), 856 (O)
- ABRAHAM, Adolphe. Publicity, 699
- ABRAHAMSON, Leonard: Adhesions in artificial pneumothorax, 790
- ABRAHI, Professor: Rheumatoid arthritis, 127
- Abscess, brain, review of book on, 772
- Abscess, epidural spinal, case of (J. Mintzman), 593 (O)
- Abscess of frontal lobe, extradermal, Jacksonian attacks in connexion with (Douglas T. Richardson), 1101
- Abscess of liver, non-tropical solitary (A. H. Holmes), 991
- Abscess, peritonissilar, haemorrhage from, 284, 371, 491, 535, 612, 657
- ACADEMY, ROYAL, OF MEDICINE IN IRELAND
- Election of Fellows, 607
- Section of Medicine.—Adhesions in artificial pneumothorax, 790—Gee's disease, 918, 1026—A correction, 1026
- Section of Obstetrics and Gynaecology.—Some personal prejudices, 917—Operation masks, 1015—Cervical myoma, 1013
- Section of Pathology.—Growth of *B. coli* in water, 919

THE PRESACRAL NERVE ITS ANATOMY, PHYSIOLOGY, PATHOLOGY, AND SURGERY*

BY

ALBERT A. DAVIS, M.D., CH.M.VICT., F.R.C.S.ENG.

HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS; HONORARY ASSISTANT GYNAECOLOGICAL SURGEON,
LONDON JEWISH HOSPITAL

In January, 1932, while engaged in the study of the innervation of the pelvic viscera, it occurred to me that some types of pelvic pain—particularly certain dysmenorrhoeas, cystalgias, and pelvic neuralgias—were possibly the result of a neuro-vascular imbalance, or, at any rate, under the control of the autonomic nervous system. I had previously been particularly impressed by the brilliant results of lumbar sympathectomy obtained by Telford and Stopford in painful neuro-vascular diseases of the extremities, and suggested the possibility of similar relief for pelvic pain by an equivalent operation.

The anatomical configuration of the nerve supply to the pelvic viscera appeared to render such a procedure technically easy, as the abdominal sympathetic fibres to these organs are collected into a median accessible bundle, immediately before entering the pelvis, as the presacral nerve (superior hypogastric plexus). Cadaveric experiment proved the truth of these facts, but a good deal of diffidence was naturally felt before recommending an operation which involved entrance into the abdomen, and which was based upon such purely theoretical grounds.

Perusal of the recent literature, however, revealed that a similar procedure had been carried out in France for some few years, under the title of "resection of the presacral nerve," an operation introduced by Cotte, professor of surgery at Lyons, in 1925. The results obtained by that author and by his colleagues were impressive, so impressive that no hesitation was now felt in advising the operation for early performance.

Our first presacral sympathectomies were carried out in March, 1932. The immediate results were excellent, and it was felt that a definite field existed for the procedure, although many of the French statements appeared somewhat hyperenthusiastic. But these operative experiences exhibited many obscure points of importance concerning the surgical anatomy of the field of operation, and before proceeding further it was resolved to investigate more completely the anatomy of the nerve itself and of its relations.

This completed, a series of seventeen patients, suffering from a variety of conditions, were subjected to the operation during the subsequent twelve months. They were mostly cases of Dr. W. R. Addis's, and fourteen were operated upon by that surgeon, in ten of which I assisted. The remaining three, by kind permission of Dr. Addis, were operated upon by me, in addition to three further cases similarly treated for other surgeons.

Each specimen of presacral nerve was examined both macroscopically and microscopically, and the physiological effects of the operation upon each of the patients studied both immediately and remotely afterwards. The results

of these anatomical and physiological researches are described in the following account, in which an attempt has been made, by correlating my researches with those already published, to provide a reasonably standard description of the presacral nerve in all its aspects.

ANATOMY

The presacral nerve is that portion of the abdominal sympathetic nervous system which lies anterior to the bodies of the fourth and fifth lumbar vertebrae, in the interval between the common iliac arteries. The term "presacral nerve" is a peculiarly unfortunate one, as the structure is usually a plexus, and is pre-lumbar in position throughout its course; but the invention of this name by the anatomical authority Latarjet, and its subsequent adoption elsewhere as a less cumbersome title than the more legitimate one of "superior hypogastric plexus," make it necessary to follow precedent in its description.

The nerve extends from a point a little above the level of the aortic bifurcation to the promontory of the sacrum, a distance of approximately 5 cm. It is formed above by the confluence of the intermesenteric nerves, long fine para-aortic sympathetic trunks arising from the solar plexus and the adjacent lumbar ganglia. After passing vertically downwards, a little to the left of the midline, the nerve terminates below by spreading out into the structure which I have ventured to name the "middle hypogastric plexus." This is an isosceles-shaped mass of considerable size, from the lower angles of which emerge the bilateral inferior hypogastric plexuses, long narrow nerve bundles which run forwards and downwards along the pelvic wall to gain the pelvic ganglion, of which they form the sympathetic root proper. The parasympathetic supply to this ganglion is furnished by the *nervi erigentes*, and some additional (insignificant) sympathetic fibres also reach it from the sacral chain. As the pelvic viscera are supplied almost exclusively from the pelvic ganglion, it will be seen that the presacral nerve contains practically the entire nerve supply to those organs, a fact which, allied to its surgical accessibility, makes the nerve the ideal site for interruptive procedures on the pelvic sympathetic.

The immediate relations of the presacral nerve are of considerable importance. In front, the nerve lies in contact with, though not attached to, the posterior parietal peritoneum, through which it is occasionally visible. Behind, it is separated from the last lumbar vertebrae by the left common iliac vein above and the middle sacral artery below. It is, however, effectively separated from these structures by being almost completely enclosed in a fairly tough bilaminar sheath formed by a condensation of the sub eritoneal areolar tissue. Although the nerve is ~~none~~ adherent to this sheath the latter is

* A Hunterian Lecture delivered before the Royal College of Surgeons of England on February 5th, 1934.

very easily dissectible from the structures in front and behind, a fact which explains the ease with which the whole nerve plexus may be separated at operation. The mesosigmoid lies to the left of the nerve, but occasionally it crosses the midline, in which case the nerve can only be reached by dissection through its layers.

The exact form exhibited by the presacral nerve—a matter of paramount surgical importance—has been the subject of much controversy. Latarjet, Bergier, Morrison-Lacombe, and Roussel all consider that in the majority of cases a clean-cut single true "presacral nerve" is present, but Hovelacque, Kalberg, Chianello, Delmas, Cordier, Ferey, Jannu, Bernard, Laux, Learmonth, Segond, Hartmann-Weinberg, and Elant all equally hold the opposite view that the usual disposition is one of several parallel nerves intercommunicating to form a plexus of varying width. The solution of these divergent views would appear to lie in the varying standards of dissection adopted, allied to a lack of appreciation of the condensation which, in formalin-prepared cadavers, often coalesces nerve fibres and fibrous tissue into an apparently single structure. Taking these fallacies into consideration it seems certain that the so-called presacral "nerve" is far more often a true plexus than a single nerve, a fact borne out in my own observations. Thus in 45 (75 per cent.) of my sixty dissections a plexus of some type was present, a single true nerve being found in only fifteen. Similarly, only two of ten operative specimens showed the structure of a single nerve.

HISTOLOGY

Specimens of the presacral nerve removed in fifteen operations, and from ten cadavers, were examined histologically, a variety of staining methods being employed in each case. These included supravital and intravital methylene-blues, modifications of the Golgi, Cajal, and Bielschowsky techniques, and the usual cold contrast methods, and all equally showed the nerve as consisting essentially of several nerve bundles lying in a fibro-fatty cellular network. The number of nerve bundles present varies widely in different specimens, according to the size of the individual plexus, and each contains many bundles of ganglion cells disposed amongst the nerve fibres. The sympathetic nerve fibres are myelinated and non-myelinated in about equal proportion as a rule (Cotte and Noel), but occasionally, as in some of my specimens, there is considerable predominance of one or other type. They are enclosed in a thick fibro-elastic sheath, and are accompanied by tiny vasa nervorum.

The ganglion cells are collected at intervals in each nerve bundle into microganglia, and correspond to the types described by Stohr and Cajal as characteristic of the sympathetic nervous system—namely, astrocytes, crown cells, and glomerular cells. Each contains a well-marked nucleus and nucleolus, and is surrounded with a varying number of tiny "satellite" cells.

This arrangement is identical with the histological structure of the intermesenteric nerves, as described by Leriche and Fontaine, a fact which, considering the continuity of the presacral nerve with them, is not surprising. Indeed, the whole abdominal sympathetic nervous system may be regarded as a vast arrangement of microscopic ganglia joining very short relays of sympathetic fibres, myelinated or non-myelinated in varying proportion according to level.

Central Connexions of Presacral Nerve

The spinal centres for the efferent fibres of the abdomino-pelvic sympathetic and parasympathetic systems lie respectively in the intermedio-lateral and medio-ventral columns at the base of the anterior horn. The former extends from the first dorsal to the second lumbar segment inclusive, to be continued in the sacral region over

a variable (disputed) number of segments. The parasympathetic extends from the fourth lumbar segment through the remaining portion of the cord.

The evidence for a centre more cranially placed tends to become more dubious with advancing research, so much so that some modern writers, including Dahl, deny their existence completely, a view shared by the writer. The problem has been admirably reviewed by Cotte, who points out that while Ferrier, Franck, Bechterew, and Meyer produced contraction of the bladder by cortical stimulation, Dennig denies the existence of a specific cortical vesical centre, while the presence of similar sub-cortical centres in the thalamus (Mislavsky, Mosso, and Pellicani), or in the corpus striatum (Czylharz and Marburg), is still more problematical. Similarly, though Gall places the genital centre in the cerebellum, Goltz, Moebius, Kraft-Ebing, and Bechterew consider it present in the cortex, while Muller and Dahl deny its cranial existence altogether. The problem, it will be seen, remains more than obscure, but the recent views would appear to be more reasonable.

Course of the Nerve Fibres

The sympathetic efferent fibres pass out in the anterior root and then, via the white rami communicantes, to the corresponding ganglion of the lateral sympathetic chain. From here they pass either to the solar plexus or mesenteric ganglia, from which they are relayed to the presacral nerve, or directly from the sympathetic chain to reach the nerve or its parent trunks in their ganglionic roots. They then pass downwards through the middle and inferior hypogastric plexuses, the pelvic plexus, and its nerves of distribution, to reach the particular pelvic viscus for which they are destined.

The peripheral cell stations in these fibres lie, according to generally accepted theory, in any of the large ganglia of the pathway, or in the small ganglia lying alongside the supplied viscera, and a considerable amount of discussion has centred round the exact site adopted for these relays. But as we have shown above, the whole abdominal sympathetic system contains thousands of microganglia in its constituent fibres, and it seems unnecessary even to attempt to postulate a few definite positions of relay, when the cell stations may be situated at any one of so many places.

The parasympathetic—sacral autonomic—fibres to the pelvic viscera pass from the medio-ventral column of the sacral cord through the anterior roots of the second, third, and fourth sacral nerves. They leave these trunks to pass, without the intervention of a lateral spinal ganglion, to the pelvic plexus, in the nervi erigentes (which for this reason have been taken as homologous with white rami communicantes). Their subsequent course corresponds to that described for the sympathetic fibres proper.

The course of the afferent autonomic fibres from the pelvic viscera, and even their existence, are equally the subject of a good deal of highly theoretical dispute. Gaskell asserted that a centripetal sensory pathway was non-existent in the autonomic nervous system, visceral sensation being conveyed via the cerebro-spinal nerves, but our post-operative studies have convinced us of the truth of the teaching of the modern French school to the contrary. These fibres probably pursue a similar course to the efferent nerves, with the exception of a detour via the posterior roots to gain the centre in the posterior root ganglion.

PHYSIOLOGY

As with the functions of the sympathetic system elsewhere, the functions of the presacral nerve may be divided up as follows:

- | | | |
|----------------|----------------|-----------------|
| (a) Motor. | (c) Sensory. | (e) Nutritional |
| (b) Vasomotor. | (d) Glandular. | |

It is, of course, impossible to divorce any one of these functions from the others, but for the sake of clarity they will be considered separately, correlated with current literature and the results of personal observation:

The Motor Function

Perusal of the literature written upon this subject reveals a bewildering variety of findings and opinions. Valentin, Heddaus, Scanzoni, Rohrig, Bartling, Korner, Frankenhauser, Cyon, von Basch, and Howden, on experimental grounds, ascribed a motor function for the pelvic organs to the lower abdominal sympathetic nerves, a view flatly contradicted by Beck and Killian, who asserted that they were inhibitory, while Kehrer, Reimann, Langley, and Gaskell suggested that *both* functions were served by these nerves. It would appear that the precise part played by the sympathetic in the motor supply of the pelvic organs must remain doubtful, but a probable cause for the divergence of views may be a variation in its action in different animals. The question of prime importance is: Is the abdominal sympathetic nerve supply to the pelvis—that is, the presacral nerve—motor or inhibitory?

A case of particular interest in connexion with this question occurred in our series. A patient was carefully observed during parturition, following resection of the presacral nerve. She was an elderly primipara, aged 42 years, yet the labour was precipitate, a most unusual occurrence in this type of patient. In addition, we have noticed as a striking post-operative sequel in all our cases that the bladder and rectum are emptied easily and frequently in the few hours following operation and subsequently, an unusual (and most desirable) event in abdominal surgery.

There is nowadays a tendency to refuse to accept the old theory of the action of the sympathetic as an inhibitor, and of the *nervi erigentes* as excitator, of contraction of the pelvic organs, but the case cited above, and the post-operative sequelae mentioned, are a striking corroboration of that mode of action. It must be admitted that the case was an isolated one, and that the phenomenon is very occasionally reproduced normally; but being quite divorced from any influence by the subject herself, and so admissible as an uncontrolled experiment, it does provide some support for the view of the presacral nerve as an inhibitor of contraction. When the presacral nerve—the sympathetic supply—is resected the sacral parasympathetic system is allowed unchecked activity in performing its function as a detrusor of the uterus, just as it is of the bladder and rectum. (It is interesting to note that three patients, previously constipated, were completely cured of this disability after resection of the presacral nerve for other conditions.)

It is possible, as was partly suggested by Bard, that the spasmodic cystalgias, dysmenorrhoeas, and rectalgias are due to irregular contraction, with spasm, of the musculature of the appropriate organ, the result of an upset of the normal sympathetic-parasympathetic equilibrium. The spasm would appear to be the result of overaction of the sympathetic inhibitory factor, removal of which, by resection of the presacral nerve, cures the condition by allowing the peristaltic action of the sacral parasympathetic supply to proceed untrammelled. This reasoning is, of course, highly theoretical, but it does suggest a factor which, in view of our cases, cannot be ignored.

The Vasomotor Function

Spielberg, von Basch and Hoffman, Rein, Langley and Anderson, and Crainicianu all stated, on experimental grounds, that the hypogastric nerves were vaso-constrictor, but Barrington holds that they are vaso-dilator, while Rohrig suggested that they were both dilator and con-

strictor. Leriche and Stricker showed that excitation of the presacral nerves produced vaso-dilatation in the pelvic viscera verified microscopically, but, on the other hand, Sweet and Thorpe found that lower abdominal sympathectomy exercised no apparent influence upon the oestrous cycle of rats. In short, some authors believe that the sympathetic is vaso-constrictor to the pelvic viscera, and the parasympathetic vaso-dilator, while the reverse opinion is held by others.

Now one of the most striking sequelae of resection of the presacral nerve in our cases has been the almost universal increase in the time and quantity of menstruation. A period of two or three days has often been lengthened to one of seven or eight, while the menorrhagia has occasionally been a source of considerable inconvenience. In addition, a striking post-operative result in all cases was the appearance of a menstrual period twenty-four to thirty-six hours after operation. This period, although possessing the characteristics of normal menstruation, had usually no relation to the normal rhythm, which remained unchanged, the next period appearing at the usual time. It would thus appear that the presacral nerve exercises a profound effect of a vaso-constrictor or vasotonic nature upon the blood vessels of the pelvic viscera, a fact which explains the abundance of the sympathetic nerve supply to the vessels of those organs.

The Sensory Function

A variety of authors have published a very considerable number of cases in which resection of the presacral nerve has produced complete and lasting relief of pelvic pain, a sequel which we have repeatedly observed in our own cases. The question remains: Has the sympathetic system in general, and the presacral nerve in particular, any sensory function in the usually accepted sense of the term? The experiments of Learmonth and of Leriche, who managed to elicit pain by traction on the central cut end of the presacral nerve in a patient and a dog respectively, and the fact that both Frigyesi and Finsterer could perform pelvic operations under local anaesthesia of the nerve, are each corroborative evidence of the existence of such a sensory function. Cotte, Lawen, Mixter, Kuntz, Aburel, and Crainicianu all support this view of the sympathetic as a conductor of pain fibres, though the majority of modern authorities, in the absence of any anatomical proof, have been so far unable to accept it. But there is no doubt that sympathectomy *does*—though not invariably—relieve pain, and that permanently; and though the hypotheses that have been advanced to explain this are all, singly, somewhat unsatisfactory, each lies within the region of possibility. They are:

1. The sympathetic system contains specific sensory fibres (Aburel).
2. The relief of pain is the result of vaso-dilatation, the subsequent increase in blood supply allowing of more efficient removal of metabolic products (Telford and Stopford, Lewis).
3. The pain is vasomotor in origin, being an upset of the normal sympathetic-parasympathetic balance. Correction of this by removal of the offending constituent—the sympathetic presacral nerve—cures the condition by restoring equilibrium (Bard).
4. The sensory fibres in the sympathetic nerves are really cerebro-spinal in derivation (Mixter).

The first theory exhibits too many unsatisfactory points for complete acceptance. It is based almost entirely on theory, and is not verified anatomically. The second is more satisfactory, but is even more theoretical, as the immediate relief of pain following sympathectomy (which would appear to support it) was not characteristic of our cases, in several of whom the first menstrual period was still more painful than the preceding. The third is an old theory revived, and, apart from its purely hypothetical basis, leaves the question open as to why the

sympathetic constituent alone should be the cause of upset. The last is unverified anatomically. One is therefore inclined to conclude that the presacral nerve has no specific sensory function *per se*, and that the relief of pain following its eradication is vaso-dilator in origin, the exact mode of action being unknown.

The Glandular Function

Barrington has shown that the hypogastric nerves control the mucin secretion of the glands of Cowper and Bartholin, and Cotte and others have cured extreme leucorrhoea by resection of the presacral nerve, a result also obtained in two of our own cases. Gaskell states in his book that the nerve cells which supply secretory fibres to purely epidermal glands—for example, the sweat glands—all belong to the sympathetic system, and are connected with the central nervous system by the thoraco-lumbar outflow of connector nerves. At the extremities of the body, where the entoderm and ectoderm come together, the ectodermal and entodermal glands may become fused to form one gland, with the result that the gland is supplied with secretory nerves both from the sympathetic and from the external nervous systems.

Now several cases of pruritus have been reported cured by resection of the presacral nerve, and we ourselves have observed similar results. There have, on the other hand, been failures, and it is tempting to ascribe the cure, on the one hand, to a glandular origin for pruritus, and the failure, on the other, to an embryological anomaly. It must, of course, be admitted that the theory of direct sympathetic sensory supply to the skin itself is untenable as an explanation of these cases. I examined every case submitted to presacral resection carefully for anaesthesia, and in only one could find even a suggestion of change.

The Nutritional Function

Takahashi found degenerative changes in the testis following excision of the hypogastric nerves, but Bacq failed to confirm these findings. Cannon and his associates have shown that no nutritional changes follow complete sympathectomy in rats, yet Leriche cured a case of kraurosis by sympathectomy. We ourselves have noticed no change of a nutritional nature in our cases. The relief of kraurosis was probably vaso-dilator in origin, and it would appear that all similar cases have a similar source. But the sympathetic supply to the skin glands is significant, and although the skin changes in some vaso-motor disorders are probably vascular in origin, it is possible that the sympathetic does exercise a separate nutritional function in the integument, although its presence there does not appear indispensable.

Summary of Functions of Presacral Nerve

The presacral nerve is motor and vaso-constrictor to the pelvic organs. In addition, it is glandulomotor, and possibly nutritional. The relief of pain which follows resection of the nerve is probably the result of the vaso-motor rather than of any sensory function, but the absence of any definite sensory fibres in its substance is by no means certain.

PATHOLOGY

Present knowledge of the pathology of the sympathetic system is both sparse and theoretical, principally on account of the fact that so many variations occur in apparently normal characteristics that the basis of normality remains extremely doubtful. We have, however, encountered changes which, even if later shown to be within the bounds accepted as normal, are of a certain interest from the possibly pathological point of view.

In several specimens changes indicative of a subacute inflammatory reaction were present in the presacral nerve. These changes were similar to those described by Cotte and Dechaume, and Jianu, and consisted in congestion of the nerve, capillary thrombi, leucocytic nodules, oedema of the sheaths, and often a small round-celled infiltration. The ganglion cells themselves, however, showed the most profound changes. In many groups some cells were complete, others showed absence of nucleus, others absence of nucleolus, the last being accompanied by an increase in the number of "satellite" cells and by thickening of the microganglion sheaths. In one specimen the single presacral nerve present was found to be permeated by squamous epithelium from a coincident carcinoma of the cervix, in a similar manner to the case reported by Ferey.

It should be noted that several sections were taken almost serially to prove that the appearances described were not due to the level of section. In many cases the changes were striking, and included loss of cell substance and fragmentation of the Nissl bodies. But these changes have been observed elsewhere in apparently normal sympathetic nerves, and before a standard of what may be considered as basically normal is adopted one must hesitate to accept the appearances described as pathological, particularly as they did not correspond with the clinical symptoms in any definite manner. On the other hand, importance is lent to these findings by the fact that in only one out of forty-one specimens of the lumbar sympathetic cord removed by them for neuro-vascular diseases of the lower extremity did Telford and Stopford find any pathological changes.

SURGERY

The physiological basis upon which is founded the surgery of the sympathetic system in general has been, and still remains, more highly controversial and doubtful in its fundamental aspects than almost any other operative rationale, and from what has been gathered from the preceding consideration of the physiology of the presacral nerve itself it will be appreciated that indications for its removal must necessarily rest upon a very insecure foundation.

Indications for Resection of Presacral Nerve

Indeed, most of the physiology of the nerve has been studied post-rather than pre-operatively, the indications being arrived at on purely theoretical grounds. As a consequence, when resection of the presacral nerve was first mooted by Cotte, these indications were somewhat limited. With advancing experience and enthusiasm, however, more and more diseases were subjected to the procedure, with the result that it became used as a sort of universal panacea for a great variety of pelvic conditions, thus repeating the very similar wave which followed the introduction by Leriche of that authority's earlier sympathetic operations (on some of which, it should be stated, Cotte's operation is merely a slight advancement).

At the present time, Continental opinion (with one or two exceptions) remains at the peak of enthusiasm. Our own experience, however, based upon operative work and combined with caution and close consideration of the physiological facts and theories, has considerably restricted our ability to agree to all the indications suggested by the French authorities, and has limited our indications to the following diseases:

1. Dysmenorrhoea.
2. Idiopathic pelvic neuralgia in both sexes.
3. Pelvic pain the result of inoperable carcinoma.
4. Cystalgia.
5. Rectalgia.

We have, moreover, severely limited ourselves in the individual cases, using the procedure as a last resort in practically all the patients subjected to it. Only those cases in which all the usual medicinal and minor operative procedures had been tried out and found insufficient were treated by resection of the nerve, and then only after consideration of the possible presence of neurosis. As an additional and most frequent indication we have added the operation to other procedures decided upon beforehand as a preventive of the persistence of pain in cases of pelvic disease in which pain has been a long-standing symptom.

Technique of the Operation

I have elsewhere described the technique of the operation of resection of the presacral nerve in considerable detail, and it is only necessary to mention here its more salient features. The abdomen is entered via a generous paramedian incision, and the bowel packed away from the operative site. The sacral promontory is then identified and the level of the aortic bifurcation noted. A longitudinal incision is made in the posterior parietal peritoneum in the mid-line, extending from just above the bifurcation to the promontory. The divided peritoneum is lifted on either side of the incision and its deep surface carefully denuded of the sub-jacent attached areolar and nervous tissue. The presacral nerve or plexus is then removed completely by excising all the fibro-nervous tissue in the interiliac space, the left common iliac vein and both common iliac arteries being carefully denuded. Haemorrhage is negligible, and it is unnecessary, and indeed inadvisable, to ligature the cut ends of the nerve.

The operation is fairly easy in the majority of cases, and if the various anatomical anomalies are kept in mind should present few difficulties.

Results of Resection

In order to assess the value of the operation a survey was made of all the cases published to date. These included cases operated upon by Cotte (200), Fontaine and Hermann (22), de Grisogono (19), Michon and Haour (17), Donaldson (16), Hamant (15), Aubert (15), Ferey (15), Walther (14), Ekkert-Petersen (9), Jianu (9), Bernard (8), Pieri (4), Mornard (3), Paolucci (3), Tirelli (3), Heitz (2), and Michon, Chianello, Oliver, Baranger, and Hallopeau one case each. Most of the cases were necessarily gynaecological, but a definite percentage of surgical cases were also included, a number which is steadily increasing with increasing publicity. Cotte himself was responsible for the majority of the operations, and his results are uniformly excellent. Most of the rest show extremely good results, though Fontaine had a death. But the periods of follow-up are very short, and many authors appear somewhat hyperenthusiastic, while close examination often reveals that the term "cure" has been used a little elastically. Again, in nearly all the published cases some other, and often major, operative procedure accompanied the presacral resection, a very fallacious addition.

Our own cases show a cure rate of approximately 50 per cent., and I would suggest that this figure represents the result which may be expected in the majority. It would appear to suggest that more care than has hitherto been the custom should be employed in the selection of cases for what is, after all, a major operation, with all the inconveniences and risks implied in that term. In suitable cases the operation is often brilliantly successful, converting a life of misery into one of at least tolerance, and there is no doubt that when the present wave of somewhat misguided enthusiasm has abated, resection of the presacral nerve will take its deservedly secure place in the select list of the permanently beneficial operations.

CONCLUSIONS

1. The presacral nerve or superior hypogastric plexus is never presacral, and rarely a single nerve.
2. Histologically it is composed of sympathetic nerve fibres and microganglia.
3. It is vaso-constrictor and motor to the pelvic viscera. Its pseudo-sensory properties are probably vasomotor in foundation. It is also glandulomotor to the superficial and deep glands, and nutritional to the external genitalia.
4. The pathology is problematical, in view of the absence of a standard of normality.
5. The indications for its resection are limited.
6. The operation itself, usually easy, exhibits occasional difficulties and dangers.

7. The results of the operation in our own series gave an approximate cure of 50 per cent., a considerably lower figure than most of the published statistics.

8. We would suggest that the operation is indicated in cases of intractable pelvic neuralgias of any type (including, of course, the dysmenorrhoeas of spasmodic origin), in which minor surgical procedures had failed to relieve; in certain cystalgias and rectalgias in male patients; as an accessory to other operative procedures in the pelvis where pain has been a characteristic of the case; and in certain rare cases of pruritus, after failure of the usual external procedures.

Acknowledgement.—I have to thank Dr. W. R. Addis for permission to investigate his cases; Professors J. S. B. Stopford and D. Dougal for the use of their anatomical and gynaecological research laboratories respectively; and Professors E. D. Telford and J. S. B. Stopford for their help and advice.

THYROID ADDICTION

BY

S. W. PATTERSON, M.D., D.Sc., F.R.C.P.,

PHYSICIAN, RUTHIN CASTLE, NORTH WALES

Thyroid addiction has not been previously described, so far as I know, and the following cases are reported as likely to throw light on other instances of obscure hyperthyroidism and for their intrinsic interest.

Case I

A woman, now aged 36, after a healthy childhood was much upset by menstruation, which began at 15; the periods were irregular in time of onset and duration, sparse rather than excessive, and always accompanied by abdominal pain, backache, vomiting, and attacks of diarrhoea. Married at 21, she had dilatation and curetting the following year, and four times inflation of the tubes during the next five years. She became pregnant once, but miscarried at the fifth month. At the age of 25 the bowels became more troublesome, with alternate diarrhoea and constipation. She was treated in Berlin with dieting, and improved; at the same time her weight was reduced by large doses of thyroid. On returning to England she relapsed, and had an operation at which the appendix and a cystic left ovary were removed. This was in 1925; the abdominal symptoms were not much improved, and the attacks continued in spite of varied treatment.

About 1929 frequency of micturition began, for which she had been cystoscoped four times, but nothing abnormal was found. In 1932 tachycardia started, and there has been a very rapid pulse since. About this time she was thoroughly investigated in Berlin; the findings were: super-acid gastric juice; spastic colon; raised blood pressure (175/95); and raised basal metabolic rate (+45 per cent.). The thyroid was not enlarged, and no evidence of substernal thyroid was found on x-ray examination. Improvement followed antithyroidin (Moebius).

SYMPTOMS

On admission to Ruthin Castle in 1933 she was a small, well-nourished woman, with pulse 140 resting in bed, and blood pressure 180/95; the heart was regular, and there was no murmur. The electrocardiogram showed rapid regular rhythm and reversed T III. The basal metabolic rate was +50 per cent.; the sugar tolerance curve was normal and the thyroid was not enlarged. There was a severe x-ray burn of the chin and chest, said to have been caused by a beauty specialist. The urine contained a few pus cells, but no bacteria, the stools a little mucus, but nothing else abnormal. X-ray examination showed residues of lipiodol injections in lumbar and gluteal muscles; the chest and stomach were normal, and the transverse colon spastic. The pelvic organs were healthy. A diagnosis of simple hyperthyroidism was made.

The symptoms were fatigue and sense of exhaustion; frequent attacks of palpitation, not sudden in onset or in finishing, in which the pulse rate was about 140; abdominal pain and generalized aching, worse when constipated; irregularity of the

bowels, small lumps of formed or semisolid faeces being passed up to thirty times a day; frequency of micturition during the day but not at night; severe hiccup, sometimes followed by vomiting; and occasional attacks of severe pain in the lower abdomen with inability to pass urine or faeces.

With treatment the abdominal symptoms lessened, but the pulse rate remained high, and progress was interrupted by crises during which the heart rate, though regular, was 130-160 per minute. At these times there was great abdominal discomfort, tenesmus, and feeling of incomplete evacuation of the bowels, with much frequency of micturition, which was not controlled by any of the measures usually efficacious. After finding some empty bottles it was possible to discover the whole story. Merck's thyroïdin was obtained in London, the labels of the bottles were washed off, and the bottles sent in with supplies of cigarettes. This procedure had been going on for at least three and a half years, and the day previous to special tests such as the B.M.R. in London a large number of tablets had been consumed. It is difficult to say how much thyroid extract had been taken, but seven empty bottles, each of which had contained 100 tablets, were found, a tablet being equivalent to about 0.5 gram of fresh gland.

This patient was a neurotic woman with dysmenorrhoea and spastic colon, whose maternal instincts were thwarted by inability to have a child, which she greatly desired. She had developed a craving for interest and sympathy, and tried to deceive everyone and to remain a medical problem and a puzzling anxiety to her friends and relatives. Even when confronted with the whole chain of evidence she denied having taken any thyroid gland for the past eight years. Her doctor wrote some months later, however, that the patient's health was now very much better, for obvious reasons.

Case II

A woman, aged 43, had had rheumatic fever over twenty years ago, also repeated attacks of quinsy until the tonsils were enucleated at the age of 30. At one time she had weighed 13 st., and had been treated with dieting and small doses of thyroid. About a year before her admission in 1929 she felt done up, and began to sleep badly after an acute streptococcal sore throat; and about six months later became much thinner and breathless. Her weight fell from 11 st. 2 lb. to 7 st. in three months. She complained of profound weakness, shortness of breath on the slightest exertion or mental excitement, fidgets and restlessness, insomnia, palpitation, disinclination for food, and periodic attacks of nausea and vomiting.

CONDITION ON ADMISSION

On admission she weighed 6 st., and was very emaciated. The heart rate was 110-130 per minute, with a mitral regurgitant murmur; the blood pressure was 125/80; and there was a mild secondary anaemia. There was no evidence of disease of the lungs. The nervous system was normal except for right nerve deafness, though at times transient diplopia was complained of. The roots of the remaining teeth were grossly septic; the digestive tract was otherwise normal. It was not possible to obtain reliable figures for the basal metabolic rate on account of the restlessness; the sugar tolerance curve was of non-diabetic type, and showed a lowered renal threshold.

A few tablets were found on making the bed, and, on searching, six packets, each containing 5-grain tablets of thyroid, and 200 to 300 tablets of aspirin and thyroid loose in a cardboard box in a cupboard. A week after their removal the pulse rate was 80 per minute and the breathing normal; the muscle movements had disappeared and the appetite improved. The septic teeth were then extracted. The patient gained 17 lb. in four weeks, and a further 1½ st. in the following six months. There was then a recurrence of symptoms of excitement, breathlessness, fidgets, and insomnia, with pulse rate of 130-160, and a number of empty bottles with thyroid gland labels were found. Improvement followed a stay in hospital of four weeks. Six months later there was auricular fibrillation and pulmonary infarction, from which a good recovery was made. During the next two years four attacks of heart failure, with decompensation and oedema, occurred. The family physician felt almost certain that the patient was continuing to take thyroid, and on admission to hospital in a fifth attack of congestive heart failure 20 5-grain tablets of thyroid were found in the fingers of a glove. A year later the general condi-

tion was somewhat better, but a partly empty bottle of 2-grain thyroid tablets was discovered in the patient's workbasket.

The psychological factors in this case were marital difficulties, to which the menopause may have contributed. Other factors were slimming and the malaise which followed the severe infection of the throat five years ago; the patient said that she took thyroid in the hope of getting a tonic effect, as small doses of thyroid had been prescribed for one of her children, who was somewhat backward.

Case III

A man, now aged 48, engaged in the import trade in the City, had all his life been stout, and at one time weighed 18 st. 2 lb. Ten years ago, after investigation of his metabolism, he was put on thyroid extract and has taken up to 5 grains a day since. He says that if he does not take the thyroid he rapidly puts on weight and is lacking in energy. Three years ago he was sent to Vichy to try and lose weight, with a view to leaving off thyroid, as palpitation was becoming troublesome. There he lost 11 lb. in eleven days, but palpitation became much worse, so that he could not walk any distance or exert himself in any way. A week after returning from Vichy, while walking, he felt giddiness, palpitation, precordial pain, and a sense of constriction in the chest. Similar attacks recurred fairly often, but he was able to resume work gradually.

He came to Ruthin Castle in 1931, his weight being then 16 st. 5 lb.; his complaint was that he was unable to walk for more than five minutes without palpitation, precordial pain, and constriction in the chest. The pulse was regular, but 76 to 80 per minute, and the blood pressure 135/80. The heart was enlarged clinically and by x-ray examination, but the sounds were clear. He was taking $2\frac{1}{2}$ grains of thyroid a day and the basal metabolic rate was + 11 per cent. With dieting, graduated exercise, and electrical treatment he lost 10 lb. in five weeks, and was able to walk for thirty minutes with comfort and without undue increase in pulse rate. We were able to reduce the thyroid to $1\frac{1}{2}$ grain twice a day.

A year later the patient's weight had again increased, and he was taking $2\frac{1}{2}$ grains of thyroid a day. He was reduced by 11 lb. in three weeks with much benefit to his symptoms, but could not be induced to do without $1\frac{1}{2}$ grain of thyroid three times a day. Last year he had increased the thyroid again to 3 grains a day, and in spite of this his weight had gone up to 17 st. After reduction of 12 lb. in three weeks he was able to walk for half an hour twice a day comfortably; but he continued to take 1 grain of thyroid twice a day.

The psychological background in this case appears to be that this man can indulge in the pleasures of the table to a greater extent, without putting on weight grossly, if he takes thyroid extract. Warned by his perturbing symptoms and on the advice of many doctors, he has reduced the amount of thyroid, but he is unwilling to give it up. The margin of safety is becoming narrower, and the electrocardiogram shows deterioration during the three years the patient has been under observation.

General Effects of Thyroid Administration

In animals a single injection of thyroid gland extract intramuscularly or intravenously lowers the blood pressure, probably from vaso-dilatation and not through the vagus, since the fall is just as much after atropine. Repeated injection in animals is followed by moist skin, wasting of the muscles, hypotension, tachycardia, and often arrhythmia, increased renal secretion, and glycosuria.¹ In normal man and healthy animals a fall in blood pressure occurs after moderate doses, and after large doses tachycardia, arrhythmia, nervousness, flushing of the skin, muscular weakness, pains in the joints, and increased perspiration.² Very large doses are said to cause exophthalmos, dilatation of the pupils, psychic excitement, tremors, and other indications of thyrotoxicosis.

In the classical case of v. Notthafft³, a man took to reduce his weight 1,000 thyroid tablets in five weeks; he lost 30 lb. in that time. At the end of the third week the neck became swollen and an irritable cough started. Then followed palpitation, insomnia, severe tremor, and ex-

ophthalmos, and at the end of the fifth week great thirst and glycosuria.

These symptoms were present in the second case now reported, and were accompanied by severe muscular wasting. This patient took large doses of thyroid continuously. In the first case, where the thyroid was taken intermittently, there was no wasting, and the severest symptom was spasmodic abdominal pain with irritation of bladder and bowel, leading to attempted evacuation two or three times an hour.

The ill effect of thyroid on cardiac muscle is well recognized, though Dryerre⁴ could find no evidence of any effect produced by thyroid extract or thyroxine on the cardiac or vasomotor nerves. In the second case the thyroid was acting on a heart already damaged by rheumatic fever, a combination that is known to be serious. The prolonged taking of thyroid in the third case appears to be affecting the heart deleteriously, as the patient is a comparatively young man coming from a long-lived and healthy stock. Monier-Vinard⁵ reports an interesting case of a woman of 50, who had taken a preparation of dried thyroid gland for ten years to keep down her weight. There were no signs of hyperthyroidism, no palpitation, tachycardia, sweating, or insomnia; but x-ray examination revealed signs of von Recklinghausen's disease of the bones. It was surmised that the bony changes were due to the prolonged administration of parathyroid substance, which had not been removed from the thyroid body in the preparation of the dried gland.

Effect on the Thyroid Itself

Krogh *et al*⁶ point out that by administration of thyroid hormone in sufficiently large amounts it is possible, both in man and in animals, to produce a thyrotoxic condition on many points resembling exophthalmic goitre. Usually, however, an overdose of thyroid substance does not produce that disease, as the condition of the individual comes back to normal within a few weeks when the administration of thyroid substance is discontinued. While examining many human thyroids these observers noted one case only which showed the histocytological picture characteristic of exophthalmic goitre. This gland came from a patient who, during five or six years, had taken a total of 1.4 kg. of dried thyroid gland. Though well aware that the large consumption of thyroid substance and the presence of exophthalmic goitre in this patient might be an accidental coincidence, they thought they could not exclude the possibility that the intake of large doses for a long time might have given rise to hyperactivity of the gland. They therefore fed guinea-pigs with thyroid. Their conclusions were that peroral administration, daily for up to a week, of large doses of dried thyroid, or subcutaneous injection of thyroxine solution, produces considerable increase in the metabolism but no change in the thyroid gland. Peroral administration of dried thyroid gland in full-grown guinea-pigs for a period of eight months produced an increased accumulation of colloid in the alveoli and a slight degree of atrophy of the lining cells in the thyroid gland.

Thyroid Addiction

The cases now reported appear to form one end of a series; at the other end are cases of hypothyroidism, which require doses of thyroid to bring the patient up to reasonable metabolic health. The man in Case II finds that by taking thyroid he can pander to his appetite and burn up more fuel, and he does this in spite of being warned of its deleterious effects. The two women are thyroid addicts. I have not been able to find reports of such cases in the literature or to hear of them from practitioners, though one doctor⁷ has told me of a patient who took thyroid surreptitiously with the idea that it would prevent lunacy, of which she lived in fear—I suppose from

some ignorant association with the idea of hypothyroidism, cretinism, and imbecility. Another practitioner⁸ has seen a patient who took thyroid in considerable doses covertly; this patient, a druggist's wife, had phlegmasia alba colens after childbirth, and she may have formed the idea that the condition of her leg was that of myxoedema. The continued use of thyroid in these cases points to there being some subjective tonic effect.

In a series of cases of thyrotoxicosis—that is, cases of not fully developed Basedow's (Graves's) disease—reported by Lublin,⁹ about half had no rise of basal metabolic rate. Some of these were "fat Basedow," and some were not benefited by operation on the thyroid, but no data are given indicating the possibility that any of these cases were similar to those now reported.

SEVERE MENORRHAGIA DUE TO CHRONIC THROMBOCYTOPENIC PURPURA, CURED BY SPLENECTOMY

BY

STANLEY J. HARTFALL, B.Sc., M.D., M.R.C.P.

HONORARY PHYSICIAN, LEEDS PUBLIC DISPENSARY AND HOSPITAL;
LEVERHULME RESEARCH SCHOLAR, ROYAL COLLEGE OF
PHYSICIANS OF LONDON

AND

CARLTON OLDFIELD, F.R.C.S., F.R.C.P.

HONORARY CONSULTING SURGEON, GENERAL INFIRMARY AND
WOMEN'S HOSPITAL, LEEDS

Cases of successful splenectomy for essential thrombocytopenia (purpura haemorrhagica) are sufficiently rare to merit detailed description. In the case here reported, in addition to the extremely satisfactory end-result which followed the operation, there were several features of special interest, which emphasize some of the less generally recognized features of the chronic form of this disease.

In the first place the patient was a young woman, in whom the only manifestation of the haemorrhagic state was a recurrent symptomless bleeding from one mucous membrane only—that lining the uterus. Thus the primary condition might easily have been overlooked altogether. Although there were no other manifestations of a haemorrhagic state it was possible, by means of a complete blood examination and a few simple clinical tests, to demonstrate that a latent purpuric state was present and that the recurrent bleeding was in all probability due to it. Finally, it was possible to make continuous detailed examinations of the blood before and after the spleen was removed, and to follow the progress of the case up to the time of publication, ten months later. A chart has been constructed which shows the most important changes observed during the first two months.

Case Record

The patient was a single girl aged 25, an office clerk, who complained of excessive menstruation, which rendered her severely anaemic and, ultimately, quite unfit for work. Her periods commenced at 14 years of age, and were at first irregular, but the loss was not abnormal. From the age of 17 to 21 years the periods were regular, and the loss normal in amount. For the last three years there had been severe menorrhagia: both the loss and the duration of the periods had increased. During this time she became severely anaemic, but would partially recover quite quickly, only to be reduced once more by another bleeding. Sometimes the bleeding was almost continuous for several months together, there being no complete cessation. At other times, when the period could be defined, clots were passed in the second half of menstruation. There was no pain, except when these clots were passed. The patient did not complain of any other trouble, but admitted that she once bled rather excessively following a tooth extraction. There was no history of spontaneous

Summary

An account is given of three cases of thyroid addiction. Two of them, both in women, were severe; the third, that of a man, was less so. The clinical notes are followed by a short discussion.

bruising. Neither of her parents nor any member of the family had ever bled excessively, or shown any symptoms of a haemorrhagic state.

Examination.—She was examined from time to time at the York County Hospital, where blood counts were made, and she was treated for a time with drugs, sera, and intramuscular whole blood, none of which effected an improvement in her condition. Examination under anaesthesia revealed no abnormality in the pelvis, and finally she was sent to one of us (C. O.) by Dr. Kathleen Bland, who wished to know if radium treatment was advisable. In August, 1933, she was admitted to the Women's Hospital, Leeds, and a complete haematological and general examination was made. The blood examination on admission was as follows: haemoglobin, 40 per cent.; red blood cells, 3,080,000 per c.mm.; colour index, 0.66; white blood cells, 6,700 per c.mm. (differential count—neutrophils 70 per cent., eosinophils 0.5 per cent., basophils nil, lymphocytes 21.5 per cent., monocytes 8 per cent.); platelets, 50,000; bleeding time, 13 and 19 minutes; coagulation time, 3½ minutes.

On clinical examination, apart from the appearance of anaemia in the skin and mucous membranes, there was nothing for special comment. The temperature was normal. The tongue, mouth, and pharynx were normal. There were no purpuric or urticarial lesions of the skin and mucous membranes. The spleen was not palpable.

Progress.—While the patient was in hospital she had two periods with a short interval between. At both, especially the first, there was severe bleeding, and the anaemia increased in severity. So critical did the condition of the patient become that two transfusions were given, and both afforded considerable temporary relief. The blood examination, together with the information provided by previous blood counts taken at York County Hospital, which had shown platelets of less than 40,000 per c.mm. on two occasions, immediately suggested the possibility of chronic idiopathic thrombocytopenic purpura as a cause for the continued excessive bleeding, despite the fact that there was no history of a purpuric rash, spontaneous bruising, or bleeding from other mucous membranes. The diagnosis was supported by the production of a fine purpuric rash in the arm subject to venous engorgement for twenty minutes by compression with a sphygmomanometer armlet. Light percussion over bony prominences, however, produced only very faint ecchymoses. The platelet count on the day these examinations were made was 60,000 per c.mm. Examination of the skin capillaries, by means of the capillary microscope under varying conditions of pressure, did not reveal any abnormality.

Operation.—In view of the critical condition of the patient and the favourable results of splenectomy, as first carried out by Kaznelson, it was recommended that the spleen should be removed in this case. Lord Moynihan kindly saw this patient, concurred, and agreed to remove the spleen. This was carried out forthwith. At the operation there was very free oozing from the abdominal wound. The spleen was slightly enlarged and was adherent to the parietes at one point, but no accessory spleens were encountered. The vessels of the pedicle were ligatured, and the organ was successfully removed. During the closure of the abdominal wall the amount of bleeding was notably less, and this was commented upon by the surgeon.

After-progress.—A blood count, taken within an hour of the ligation of the splenic vessels, was as follows—one taken the day before operation is shown for contrast:

	One Day before Operation	One Hour after Operation
Haemoglobin ...	50 per cent.	36 per cent.
Red blood cells ...	3,550,000	2,500,000
White blood cells ...	7,100	6,000
Platelets ...	30,000	85,000
Bleeding time ...	19 min.	2½ min.

The subsequent progress of the case can best be followed in the chart appended. The chief interest naturally lies in the quantitative changes in the platelets and in the improvement in the bleeding time. The former increased rapidly after splenectomy, and reached a maximum of 970,000 per c.mm. on the fifth day (much earlier than was expected); they then fell quickly to about 650,000 on the seventh day, and, after a temporary rise again on the eleventh day, reached a level between 500,000 and 600,000, where they remained until the twentieth day. They then fell gradually below

The most obvious feature of the microscopical picture is the increase in the pulp. This is composed of a congeries of well-defined blood sinuses, with fairly large and prominent lumina. These still contain numerous red blood corpuscles, together with many leucocytes. The walls are thickened and cellular, and the endothelial lining is unusually prominent and well defined. The Malpighian bodies are widely separated and rather small in size, but otherwise present in general, normal characters. In several places, however, small foci of cellular proliferation of a peculiar kind are present, nearly always in relation to, or actually embedded in, a Malpighian body. They are composed of loosely arranged aggregations of large cells of endothelioid or reticular type, each with abundant cytoplasm and round or oval nuclei, with a clear-cut nuclear membrane and from one to four nucleoli. The cells are irregular in size and shape, and ill-defined at the margins, but there is no evidence of fusion to form giant cells. Apart from these

Chart constructed to show the changes in the haemoglobin, red blood corpuscles, reticulocytes, platelets, bleeding and coagulation time, (1) at various times over a period of two years before admission, (2) after admission and immediately before operation, (3) after the operation of splenectomy.

500,000 and the last count made was 390,000, six months after the operation. The bleeding time improved immediately after the operation, being reduced from nineteen to two and a half minutes. There was a reticulocyte crisis of 11 per cent. on the seventh day. The red cells and haemoglobin slowly increased under the influence of iron by mouth, and were practically normal after three months.

In other respects the post-operative course was uneventful. During the few days when the platelets were so extraordinarily numerous, thyroid extract was given to minimize the chance of thrombosis. The effect upon menstruation was remarkable. On the sixth day after operation the patient had a short period lasting three days—"the first normal period for years." A period was then missed, and thereafter they became perfectly regular, the loss being normal in quantity, and lasting four or five days only. The patient has increased in weight, and has resumed her work and all her social and athletic activities.

Pathology of the Spleen

The greater part of the convex surface was covered by old fibrous adhesions and tags of attached omentum. On the concave aspect there was a small area of similar adhesion across the middle. The organ after removal was not enlarged, being about normal in size, but this was after a quantity of blood had drained away. On section, the cut surface was smooth, homogeneous, and congested, with the Malpighian bodies small and widely separated. The tissue was fairly firm but not fibrous.

negative features the appearance of these follicles closely resembles that figured and described by Kettle (*Journ. Path. and Bact.*, 1919-20, xxiii, 413, Fig. 7) in one of his cases of splenomegaly associated with secondary anaemia. As in Kettle's case, the resemblance to early tubercle follicles is very close, but central caseation as well as giant-cell formation is absent. In contrast to Kettle's case, there is little or no formation of collagen fibrils at the periphery of the foci. A search for tubercle bacilli yielded negative results. It is suggested that this appearance may be an early example of the lesion described by Kettle.

Summary

A case is recorded of chronic thrombocytopenic purpura in a woman aged 25. The only symptom was recurrent menorrhagia causing severe anaemia. There was no bleeding from any other source, no purpura or spontaneous bruising, and the spleen was not palpable. The latent purpuric state was revealed, however, by the capillary resistance test. Splenectomy has cured the menorrhagia and restored the patient to health. The quantitative changes in the blood before and after operation were followed daily, and are presented as a chart, and the histology of the spleen is described.

We are indebted to Professor M. S. Stewart for help with the histological report.

WEIL'S DISEASE AMONG SEWER WORKERS IN LONDON

BY

N. HAMILTON FAIRLEY, M.D., D.Sc., F.R.C.P.

ASSISTANT PHYSICIAN AND DIRECTOR OF PATHOLOGY, HOSPITAL
FOR TROPICAL DISEASES, LONDON; LECTURER, LONDON
SCHOOL OF HYGIENE AND TROPICAL MEDICINE

Since the causative organism was first demonstrated in Japan by Inada and Ido in 1915, Weil's disease (spirochaetal jaundice, infective jaundice, leptospirosis) has been recognized in many different countries, and during the war it affected German, French, and British troops on the Western Front. Schüffner¹ (1934), who reported that during the past ten years 452 cases have occurred in Holland with forty-six deaths—that is, 10.2 per cent. mortality—distinguishes three pathogenic leptospirae which may affect man in Europe: (1) the cosmopolitan *L. icterohaemorrhagiae* in rat and dog, the cause of classical Weil's disease; (2) *L. canicola*, causing a specific canine disease, but capable of infecting man (one case); and (3) *L. grippotyphosa*, the infective agent of swamp fever of Eastern Europe. Other strains have been encountered in the Dutch East Indies, Malaya, and the Andamans.

Weil's disease has been diagnosed among sewer workers on the Continent, but no such cases have been recorded in Great Britain, though in London Foulerton² (1919) found that four out of 101 rats harboured leptospirae pathogenic to guinea-pigs, and Stevenson³ (1922) reported leptospirae in 30 per cent. of rats examined. Only one authentic human case originating in England appears in the literature—namely, that described by Manson-Bahr⁴ (1922) from the Albert Dock Hospital in a seaman developing the disease four days after falling into the Thames at Gravesend. Wenyon and Brown⁵ isolated *L. icterohaemorrhagiae* from the citrated blood of this patient, collected on the seventh day of the disease.

During 1923 an epidemic of jaundice of unknown origin broke out among miners working in certain coal pits in East Lothian. Gulland and Buchanan⁶ (1924) investigated the epidemic. There were some eighteen cases with jaundice, and of six patients admitted to the wards of the Royal Infirmary two died. Clinically they were typical, and followed a course similar to that in the cases occurring in British troops in France, described by Stokes and Ryle⁶ (1916), and Dawson, Hume, and Bedson⁷ (1917). Guinea-pigs inoculated with urine from the East Lothian cases died with typical post-mortem findings, and *L. icterohaemorrhagiae* were demonstrated. The pits where the disease was contracted were all "wet," and rats, some of which were proved to harbour leptospirae in the kidneys, were plentiful there. Later, when investigating carrier hosts, Buchanan⁸ (1927) showed that sixty-one out of 166 wild rats were infected with virulent leptospirae, and found leptospiral organisms in fungal slime hanging from the roof of the mines and in pit-surface waters. Inoculation of a certain specimen of slime into two guinea-pigs produced typical leptospirosis. He concluded as a result of experimental investigations in the guinea-pig, and from conditions in the coal mines, that human infection was more likely to arise as a result of leptospiral invasion through skin abrasions or by way of the eye and the nasal mucosa from contaminated hands.

Case History I

A sewer worker of fine physique, aged 25 years, was admitted to the Hospital for Tropical Diseases on May 17th, 1934, with jaundice and a history of five days' fever.

PAST HISTORY

The patient, who was an ex-soldier, had returned from India in November, 1932, after seven years' service. During the voyage home, he stated, he had had an attack somewhat similar to the present one, with generalized aching pains, anorexia, lassitude, and (?) jaundice. He was kept in hospital on board ship for about sixteen days, and was treated with quinine, although malarial parasites were not found. Since then he had had at least two milder attacks, without jaundice, which subsided in two to three days after quinine therapy.

PRESENT ILLNESS

The present illness started on Saturday evening, May 12th, 1934, with aching pains in both shoulders and neck, which later became generalized; there was associated headache and shivering, but no nausea or vomiting. The following day his legs "felt too weak for him to get up." On the third morning (Monday) he went out to work, but in the afternoon was so ill that he had to return to bed. On the fourth day he began to cough up blood and black sputum. Jaundice appeared on the fifth day, and the urine was extremely dark coloured; constipation had been marked for several days. He was now seen by Dr. Rosen, who next day noted that the jaundice was increasing and sent him to hospital (May 17th).

PHYSICAL EXAMINATION

The patient was prostrated and markedly jaundiced. The conjunctivae were injected, and had a deep icteric tinge, which also involved the skin and mucous membranes. The temperature was 100.4° F., the pulse 118, and respirations 28.

Examination of the heart and lungs revealed no abnormality. The abdominal wall moved moderately with respiration, but on deep palpation there was definite generalized tenderness, most marked in the right iliac fossa. There was very little rigidity immediately on palpation, but the abdominal muscles contracted after deep pressure was applied, and the patient flexed the knees, grunted, and obviously resented what was being done. Digital examination of the rectum elicited some tenderness anteriorly, but next day this had entirely disappeared. The rectum was then ballooned out, and there was no evidence of any pelvic collection of pus. There was no demonstrable enlargement of the liver or spleen, although, owing to muscular tenderness, examination was difficult. The pupils were pin-point in size and reacted sluggishly, if at all, to light. The tendon-jerks of the arms and legs were absent and the calf muscles exceedingly tender. The plantar reflex was flexor in type.

LABORATORY INVESTIGATIONS

Blood collected under paraffin was oxalated and centrifuged and the plasma examined spectroscopically: no trace of haemoglobinaemia was found. Malarial parasites were absent from the blood smears, in which anisocytosis and a polymorphonuclear leucocytosis were evident. The blood count showed: red cells, 4,300,000 per c.mm.; haemoglobin, 90 per cent. (Haldane); colour index, 1.0; leucocytes, 18,000 per c.mm., of which there were 90 per cent. neutrophil granulocytes and 10 per cent. lymphocytes. Van den Bergh reaction: direct, prompt biphasic reaction; indirect, positive (24 units). Eight ounces of urine were obtained by catheterization: specific gravity, 1010; acid reaction; albumin ++; acetone, a trace; sugar, nil; bile pigments ++; bile salts ++; urobilin ++. A few pus cells but no casts were observed in the centrifuged deposit. Spectroscopic examination revealed an absence of both oxyhaemoglobin and methaemoglobin.

These findings eliminated blackwater fever from the differential diagnosis, which was now considered to lie between some form of toxic jaundice, Weil's disease, and suppurating pyelophlebitis, the abdominal condition suggesting the possibility of peritonitis. Mr. A. H. McIndoe saw the patient in consultation from this standpoint: it was decided to withhold food per os and give large intravenous injections of glucose (5 per cent.) in normal saline, 1 litre of which was given at 6 p.m. and repeated at 11 p.m.

PROGRESS OF CASE

The patient vomited eight ounces of blood and had a severe epistaxis. Herpes was present on the lips. A catheter was passed, but only a few drops of bile-like material were obtained. Massive intravenous glucose injections were continued. Blood cultures on different media were negative. As leptospirosis was suspected on clinical grounds citrated blood was sent to Dr. C. M. Wenyon of the Wellcome Bureau of Science for inoculation into guinea-pigs.

On May 19th the condition was worse, with headache, epistaxis at frequent intervals, and a troublesome hiccup. Anuria and obstinate constipation continued. Intravenous injections of glucose were maintained. On May 20th the patient was drowsy. Melaena was present, and the bowels were opened five times. Epistaxis and hiccup still occurred. Faeces were negative for ova and protozoa. Intravenous injections were continued. On May 21st the mental state was confused and drowsy. The following day the patient was desperately ill and intensely jaundiced, with oedema of the subcutaneous tissues and ascites. Intravenous injections were stopped.

Wassermann reaction negative. Van den Bergh reaction: prompt biphasic reaction, indirect positive (41 units). Blood urea: 346 mg. per 100 c.cm. Urine obtained by catheterization showed albumin ++, bile pigments ++, bile salts nil. Centrifuged deposit contained a few leucocytes and epithelial cells, with an occasional red blood corpuscle but no casts. Bilirubin crystals and amorphous urates were present.

The patient died at 7.45 a.m. on May 23rd.

POST-MORTEM FINDINGS

A necropsy was performed by Colonel F. P. Mackie, I.M.S. The body was well nourished, the skin was deeply jaundiced, and the subcutaneous tissues of the neck, feet, and legs were oedematous.

Abdomen.—Much clear, bile-stained fluid was present in the peritoneal cavity. There were submucous haemorrhages in the cardiac portion of the stomach, and the small intestine was congested. The liver was very large (87½ oz.), soft in consistency, and a yellowish chocolate colour on section; the contents of the gall-bladder consisted of brownish-black fluid, which contained bile salts but no bile pigment. There was no bile duct obstruction. The spleen weighed 12 oz., and was dark in colour and firm in consistency, with prominent Malpighian bodies on section. The kidneys were large and semi-lobed, the right weighing 12 and the left 12½ oz.: the capsule stripped readily, the cortex appeared swollen and yellowish red in colour, while the medulla was deeply congested. The mesenteric glands were somewhat prominent, and the pancreas and suprarenals were normal.

Thorax.—The endocardium was bile-stained; there was oedema of the lungs and free fluid in the pleural cavities.

MICROSCOPICAL FINDINGS

The sections of special interest were those of the liver and kidney.

There was cellular infiltration of the periportal zone of the liver and cloudy swelling of the polygonal cells, but no focal or general necrosis. Malaria pigment was absent from Küpffer's cells, the liver cells contained haemofuscin, while the infiltrating cells in the vicinity of the bile ducts were mainly neutrophils with occasional macrophages.

There was widespread destruction of the tubular epithelium of the kidney, with no change in the glomeruli other than some surrounding leucocytic infiltration, while some of the straight tubules were plugged with debris, red blood corpuscles, and disintegrating haemoglobin. Immediate examination of liver smears with Indian ink failed to reveal leptospirae, and sections of the liver, spleen, and kidneys stained by the Levaditi method were also negative.

In the absence of demonstrable leptospirae the cause of death was assessed as (1) toxic jaundice, (2) nephrosis.

LABORATORY DATA

Major H. C. Brown, I.M.S., subsequently reported from the Wellcome Bureau of Scientific Research that both the guinea-pigs inoculated with blood collected on May 18th—the seventh day of the disease—had sickened, and that necropsy revealed the characteristic post-mortem features of Weil's disease—

jaundice and visceral haemorrhages. Typical leptospirae were demonstrated by dark-ground illumination in emulsion of liver pulp from one animal and in the heart blood of both. This strain was isolated in pure culture, and subcultured in series on Fletcher's medium.

Professor Schüffner also reported that the serum of the patient, collected on May 22nd (that is, on the tenth day of the disease), gave a strongly positive agglutination reaction (1 in 1,000) with the typical "Weil" strain, whereas it was absolutely negative for *L. canicola* and the "Rachmat" strain from the Dutch East Indies.

Comment on Case I

From a clinical point of view this case was typical of Weil's disease, presenting the usual sudden onset with rigor; extreme prostration; muscular tenderness; severe jaundice on the fifth day; multiple haemorrhages, including epistaxis, melaena, and haematemesis; herpes; renal involvement with albuminuria, oliguria, anuria; and, finally, death on the eleventh day. Interesting features were the severe constipation, the temporary non-passage of flatus, tenderness on deep palpation of the abdominal muscles of such a nature as to arouse suspicion of peritonitis, and free fluid in the abdominal cavity. The terminal waterlogging was probably related to the massive intravenous injections of glucose in an anuric subject; the nitrogenous retention at this time was marked, the blood urea equalling 346 mg. per 100 c.cm. The jaundice itself was very intense, the bilirubin content of the blood equalling 41 van den Bergh units, or 20.5 mg. per 100 c.cm. Early in the disease the urine contained both bile pigments and bile salts, but before death the latter had disappeared. At necropsy, on the other hand, the brownish-black fluid contents of the gall-bladder contained only bile salts and no bile pigment, the iodine test and the van den Bergh both being negative. Evidently, during the latter phase of the illness, the liver had lost the power of excreting bilirubin, while retaining its excretory function in regard to bile salts; the reverse happened in the kidney.

Since returning from India this patient had been mostly unemployed, but twenty-two days before the onset of his illness he joined a gang of workmen engaged in repairing a sewer in Chesham Street, Hyde Park Corner. His work included chiselling out the old bricks, the inner surfaces of which were stated to be covered with a slimy deposit from the sewer, and in other ways he came in contact with sewer water. Furthermore, being new to this occupation, his hands were badly contused and abraded by the hammer used for the work. His father, who had been a flusher of sewers for twenty-seven years, stated that rats were common in the sewers, and that jaundice was a not uncommon complaint among sewer labourers and builders in London. As an instance of this, a fatal case of jaundice in a sewer worker was cited where the coroner had given an "open verdict." The records of this case were consulted, and the facts, based on medical and lay evidence, were as follows:

Case History II

A sewer repairer, aged 34 years, who enjoyed excellent health, came home on October 14th, 1933, and in the evening complained of feeling ill with a sore throat; shivers and rise of temperature followed. Next day he felt better, and attempted to get up, but had to go back to bed. Anorexia and constipation were marked. On the third day (October 16th) he was seen by his panel doctor, who reported he had a red and slightly ulcerated throat, and was suffering from acute tonsillitis. His general condition, instead of improving, became worse: he was markedly prostrated, and had difficulty in moving the limbs. On the fifth day he developed jaundice and passed a blood-stained stool. The jaundice deepened, his condition became more and more grave, and he was removed to hospital on

the ninth day, dying four days later—that is, on the thirteenth day of the disease. A necropsy by the medical officer revealed jaundiced organs, a liver normal to the naked eye, and an enlarged gall-bladder, but no gall-stones were found anywhere in the biliary system.

The panel doctor, in his statement, said "there were no signs of liver disease, and it was difficult to account for the jaundice except on the grounds of some form of toxic poisoning which, in fact, it seemed to be." A foreman employed in the same firm as the deceased said that the work of the deceased on the last day had been to take bricks down to the bricklayers inside the sewer and to remove any rubbish down there. He made no complaint of having smelled gases, but he complained of foul smells; the man-holes were open every day, so gases could not accumulate. It was suggested that certain sewer gas, such as sulphuretted hydrogen, might cause jaundice, and a pathologist stated that he found sulphæmoglobin, 2 to 3 per cent., in the blood, and had searched for arsenic and phosphorus, but had found none. The coroner returned an "open verdict—toxic hepatitis—but there was no definite evidence to show how or by what means the toxic condition had arisen."

Past Jaundice in Sewer Workers

The facts regarding this case appeared so similar to Case I that it was decided to inquire into the history of some of the sewer workers who had suffered from jaundice in the past, and also to subject their blood to certain specific leptospiral agglutination tests, to which Schüffner and his colleagues have recently made such valuable contributions.

AGGLUTINATION REACTION IN WEIL'S DISEASE

Professor Schüffner was actually lecturing in London on leptospirosis at the time Case I was admitted to hospital, and later, when I wrote informing him of my suspicions regarding an endemic focus of Weil's disease among sewer workers in London, he generously agreed to test sera from these cases in his own laboratory at Amsterdam, specimens being sent across by air mail.

Weakly formalized (1/2 per cent.) cultures of leptospiræ, which prevent lysis, were used as antigen, and each serum was tested against the classical "Weil" strain, *L. icterohaemorrhagiae*, the East Indian human strain "Rachmat," and the dog strain, *L. canicola*. In addition, living cultures of *L. icterohaemorrhagiae* were employed as antigen in most instances. In performing the tests sera are diluted 1 in 10, 1 in 30, 1 in 100, 1 in 300, 1 in 1,000, etc. The reaction is highly specific, weak positive being indicated by 1 in 10 and 1 in 30 dilutions, and strong positive reactions by dilutions of 1 in 100 and upwards. Control sera have never shown agglutination in Schüffner's hands, even in a 1 in 10 dilution.

Residual agglutinin persists for many years, and Postmus⁹ (1933), re-examining Schüffner's old cases, found positive reactions of from 1 in 100 to 1 in 300 over a range of from 218 to 6,066 days after the disease. The last patient contracted his jaundice in the war, and his serum gave a positive reaction (1 in 300) sixteen years and seven months later. Obviously, therefore, the reaction affords a very important index to past infection.

Case II had been employed at the Kensal Road sewer when he contracted his fatal malady, and the first workman with past jaundice to be interrogated (Case III) stated that he also had developed his illness while working there some eighteen months previously. His case history is epitomized below.

Case History III

The patient, aged 28 years, had been employed for five years in rebuilding sewers. On December 26th, 1932, he felt ill, and went to bed with aching pains in the feet; in the morning he had severe stiffness and pains in the legs, and next day his doctor reported a high temperature and diagnosed influenza. Anorexia and vomiting were present. On December 31st (the sixth day of the illness) jaundice developed, and subsequently increased in severity. Constipation was marked; the motions were black like tar (melæna); and the urine was dark yellow. The jaundice persisted for several weeks, and the patient lost his hair during convalescence.

Agglutination.—Serum collected eighteen months after jaundice—"Weil" strain + (1 in 1,000); "Rachmat" strain 0; dog strain + (1 in 100).

The clinical history, combined with the high titre agglutination of the serum when tested against the classical "Weil" strain of leptospira, shows that this patient had undoubtedly suffered from true Weil's disease. The fact that he contracted his infection some ten months before Case II when working in the same sewer entirely supports the view that Case II also died from the same disease.

Case History IV

The patient, aged 22 years, was repairing the Priory Street sewer, Bromley. On June 12th, 1933, he felt weak, and two days later had cold shivery feelings also. There were severe pains in the legs. By June 15th he could not stand up, and went to bed. Generalized jaundice set in on June 17th (that is, the sixth day), and persisted for nearly six weeks. The motions were clay-white and the urine was black. In the early stages the muscles were so tender that he could hardly bear being touched. Catarrhal jaundice was diagnosed by his panel doctor. During convalescence most of his hair came out.

Agglutination.—Serum collected twelve months after jaundice—"Weil" strain, both living and formalized cultures; + (1 in 300); "Rachmat" strain + (1 in 30); dog strain + (1 in 10).

Case History V

The patient, aged 28 years, was engaged on the same sewer. At 5 a.m. on August 19th, 1933, while at work, he suffered from a shivering attack with fever and aching pains in the head and body, but stayed on until 9 a.m. next day, when he went home to bed. He did not get up again for about two months. He raved for the first three days, and was diagnosed as a case of influenza and bronchopneumonia by his panel doctor. Jaundice developed on the fourth or fifth day; fever also was present. The jaundice increased; vomiting was severe; he coughed up blood and had tarry black motions. The limbs ached, and the legs felt like "falling off." The jaundice lasted nearly a month, and he was home almost eight weeks after that. His eyes became troublesome, necessitating treatment at Moorfields Hospital, and he did not return to work for six months.

Agglutination.—Serum collected ten months after jaundice—"Weil" strain, living cultures + (< 1 in 300), formalized cultures + (1 in 300); "Rachmat" strain + (1 in 10); dog strain + (1 in 30).

Case History VI

The patient, a labourer aged 31 years, was also handling bricks in the sewer at Bromley. He came on to relieve another worker, and thirty-six days later, on November 13th, 1933, developed shivering, fever, and backache, and went home to bed. He became very restless and light-headed, and next morning lacked the strength to get up. He tried to shave, and when a looking-glass was brought to him states he was astounded to find he was yellow. The urine later became black and the stools putty-coloured, and he could neither micturate nor get the bowels to act. On November 19th, 1933, there was coffee-ground vomit. Herpes also was present, as well as severe loin pain. He was jaundiced for six weeks while in hospital, and this had not completely cleared when he was discharged. He was about four months away from work, had trouble with his eyesight, and lost his hair in convalescence.

Agglutination.—Serum collected seven months after jaundice—"Weil" strain, living cultures + (1 in 1,000), formalized cultures + (> 1 in 300); "Rachmat" strain 0; dog strain 0.

Comment on Cases IV, V, VI

These three cases are of special interest as they had all occurred within the last year, the patients having contracted the illness when working in sewers at Bromley some twelve, ten, and seven months previously. Their histories are very typical, except that the jaundice in Case VI appeared early—according to the patient's statement on the second day of illness. The agglutination reactions were of high titre in all instances, and leave no doubt regarding the diagnosis.

Case History VII

The patient, aged 32 years, had been engaged as a sewer labourer since January, 1932. One Saturday evening in June, 1933, while working at the Wick Road sewer, Hackney, he was seized with a shivering attack, loin pain, and fever. Generalized pains, especially involving the head and neck, followed. He spent next day in bed, and on Monday went over to Peckham, took to bed, and was treated by his panel doctor. On Tuesday the temperature was 103.6° F., and on Wednesday (fifth day) jaundice with itching of the skin was noted. The motions now resembled "white paste," and were sometimes admixed with dark red blood. Epistaxis, haematemesis, and labial herpes subsequently developed. Weakness was extreme and the pains in the legs excruciating. He was in bed for two months, and the jaundice itself lasted six weeks: even then a yellow tinting of the conjunctivae persisted some time.

Agglutination.—Serum collected two years after the jaundice—"Weil" strain, living cultures + (1 in 1,000), formalized culture + (> 1 in 300); "Rachmat" strain 0; dog strain + (1 in 30).

Case History VIII

A sewer repairer, aged 60 years, stated that one Sunday evening in March, 1929, he felt cold and shivery, and developed fever. The preceding day he had been quite fit, being engaged in chiselling out brickwork at the Alexandra Road sewer, Kilburn. On Monday he had a severe headache and was so weak that he could not lift his head from the pillow; the following day his panel doctor diagnosed influenza. On Wednesday (fourth day) jaundice first appeared; this increased in intensity, and the skin became exceedingly itchy and the urine very dark. The stools were tarry black (melæna). Jaundice persisted for about six weeks, and during convalescence his hair came out "in handfuls."

Agglutination.—Serum was collected five years and four months after the jaundice—"Weil" strain, living cultures + (1 in 30), formalized cultures + (1 in 30); "Rachmat" strain 0; dog strain + (1 in 10).

Case History IX

The patient, aged 40 years, stated that in April, 1926, when doing brickwork in a Tottenham Court Road sewer, he had a headache and began to feel cold and shivery. He collapsed that evening and became semi-conscious; he remembers very little about his illness, which lasted six to seven weeks, except that he was intensely jaundiced, his skin was extremely irritable, and the pain in his muscles was so great that "he screamed when touched." It is noteworthy that prior to the onset of jaundice pleurisy was first diagnosed, and later, owing to abdominal tenderness, appendicitis was suspected.

Agglutination.—Serum was collected eight years and two months after the jaundice—"Weil" strain, living culture + (> 1 in 300), formalized culture + (1 in 100); "Rachmat" strain + (1 in 10); dog strain + (1 in 10).

Case History X

The patient, a brother of Case III, stated that he had fever about Christmas, 1922, when cutting out brickwork at a sewer near St. Pancras. Intense jaundice followed and persisted for several weeks.

Agglutination.—The serum was collected twelve and a half years after the jaundice—"Weil" strain, formalized culture + (1 in 100); "Rachmat" strain 0; dog strain + (1 in 30).

General Discussion

Most of the sewer workers in this series were treated by their panel doctors, and in the early stages, prior to the onset of jaundice, the provisional diagnosis was generally some general infection like influenza or tonsillitis. The absence of evidence of local hepatic disease, such as gall-stones in the common duct, naturally led to the diagnosis of catarrhal jaundice in those patients who recovered, while fatal cases, such as Case II, which appear generally

to have been admitted to hospital in the later stages of the illness, were regarded as due to toxic or obstructive jaundice of unknown causation. Several such cases among sewer workers have been brought to our notice during the course of this very limited inquiry.

When viewed in retrospect, the occupational relationship to sewer rats, the course of the disease, and its symptomatology leave little doubt on purely clinical grounds that for many years sewer workers in London have been subject to the ravages of Weil's disease. This is entirely supported by the mode of onset, the great prostration, the pain and muscular tenderness, the prolonged and severe jaundice generally commencing about the fourth to the sixth day, the tendency to haemorrhage from mucous membranes, and the occurrence of patients dying from the ninth to the thirteenth day of the illness; all these features the case histories definitely reveal. Loss of hair, sometimes amounting to actual baldness, was a not infrequent sequel. What little doubt regarding diagnosis might exist on the basis of these data is immediately dispelled when the results of the agglutination tests performed by Professor Schüffner are considered. In seven out of eight cases strongly positive agglutination reactions were demonstrated, the titre of the serum varying from 1 in 100 to 1 in 1,000 in different instances when living or formalized cultures of the classical "Weil" strain, *L. icterohaemorrhagiae*, were employed. The remaining serum (Case VIII) alone gave a weak positive reaction (1 in 30), but, as control sera do not react even in a dilution of 1 in 10, here also the serological evidence supports the clinical diagnosis. Three out of eight sera had lower titre group reactions (1 in 10 to 1 in 30) with the Dutch East Indian "Rachmat" strain; while seven out of eight presented group reactions with the dog strain, *L. canicola*, the titre in three being 1 in 10, in three others, 1 in 30, and in one instance (Case III) 1 in 100. Group agglutination of this nature, to which various leptospirae are prone, can be distinguished from specific agglutination by absorption tests where necessary.

One other case of jaundice in a sewer worker (as long ago as 1912) was also investigated. The history was atypical, the patient stating that at the time he had been definitely diagnosed as a case of typhoid and that jaundice had occurred as a later complication. On the supposition that the diagnosis might have been erroneous, his serum was sent to Professor Schüffner as that of Weil's disease: the agglutination reactions for all strains were, however, negative.

These serological findings, no less than the clinical evidence, prove conclusively that the cases cited have suffered from true Weil's disease, and that this disease has been endemic among London sewer workers for at least twelve and a half years.

Mode of Infection and Treatment

The present series of cases comprised sewer labourers engaged in repairing or rebuilding old sewers; none of them were "flushers," whose duty it is to clean the sewers. Amongst other duties their work consisted in chiselling away and removing the old brickwork in a section of sewer under repair, and during this process the skin of their hands was often traumatized. The inner surfaces of bricks lining the sewer are covered with a slimy deposit, and all stated that soiling of the hands was unavoidable. The sewers in which the repair work was undertaken were wet and, especially in the smaller sewers of from four to six feet in diameter, the work had to be undertaken in a very confined space. Contact with sewer water was inevitable, though waders were worn.

The incidence of sewer rats was said to vary in different sewers, and some of the men stated that it was occasionally

necessary to remove dead rats from sewer water. As rats in London are known vectors of *L. icterohaemorrhagiae* the opportunities for human infection with leptospirae must be considerable under the conditions described. Buchanan* (1927) found that the fungal slime in the East Lothian coal pits contained leptospirae pathogenic to guinea-pigs, and similar inoculation experiments with slime from London sewers might well yield positive results.

A discussion on prophylactic measures hardly falls within the scope of the present paper, but it is obviously important, as approximately only 50 per cent. of cases of leptospirosis develop jaundice, that a serological as well as a clinical investigation of sewer workers for infection with Weil's disease should be undertaken to determine the real extent of this disease: this must be considerable, since the present inquiry was only made at odd times over a period of a few weeks, and was restricted to a limited section of sewer workers employed by a large firm of London contractors.

Specific therapy in the form both of convalescent serum and of anti-leptospiral serum (B.W. and Co.) is available, and the institution of such treatment, especially if carried out prior to the onset of jaundice, should undoubtedly save life. For early diagnosis both clinical and laboratory investigations, such as the centrifugation of blood to concentrate leptospirae, are essential, and for this purpose the early centralization of doubtful cases in one hospital might prove advisable. Prophylactic leptospiral vaccines might also prove valuable in sewer workers.

Summary

1. A widespread and hitherto unrecognized focus of Weil's disease affecting the sewer labourers of London has been demonstrated.

2. Its existence for at least twelve and a half years has been conclusively proved.

3. The mode of acquiring infection and certain other issues are discussed.

I am greatly indebted to Professor Schüffner, Dr. C. M. Wenyon, Major H. C. Brown, and Colonel F. P. Mackie for their invaluable assistance, and also to Dr. R. H. Wiseman and others in connexion with certain of the case records.

R. S. F. Hennessey (*East African Med. Journ.*, May, 1934) records an outbreak of eighty-two cases of typhus which occurred in the Western Province of Uganda in June, 1932. The general manifestations of the disease corresponded more or less closely with those of the European form of typhus. Thirty-six were males and forty-six females; sixty-three out of seventy whose ages had been recorded were between the ages of 10 and 30; practically all were peasants. There were eight deaths—a mortality of 9.7 per cent.—four of the fatal cases being males and four females. The high degree of infestation with the body louse made it probable that the insect played an active part in the transmission of the disease, and this view was confirmed by inoculation of guinea-pigs, who developed a definite form of pyrexia of from four to ten days' duration.

CASE OF SPIROCHAETAL HAEMORRHAGIC JAUNDICE (WEIL'S DISEASE)

BY

W. G. WILLOUGHBY, M.D.LOND.

MEDICAL OFFICER OF HEALTH, MEDICAL OFFICER, ISOLATION HOSPITAL,
EASTBOURNE

AND

A. G. SHERA, M.A., M.D.CAMB.

CONSULTING PATHOLOGIST, EASTBOURNE HOSPITALS, AND TO THE
FAVINGHAM COUNTY COUNCIL

The rarity of Weil's disease in this country makes it worth while to publish a case which has occurred in Eastbourne.

Clinical History

A female Post Office employee, aged 23, was admitted to hospital on April 7th, 1934. The condition on admission was as follows: very considerable jaundice, enlarged glands in general, especially the left parotid, swelling of the neck, swollen tongue, erysipelatous condition of the face, which was much swollen, and general inflammation of the skin, with commencing desquamation all over, particularly of the hands and feet. There were two small bullae similar to pemphigus on the fingers. The left conjunctiva was half covered with haemorrhage, and there were haemorrhages all over the skin from the size of a shilling downwards, especially on the arms and abdomen. There was also rectal haemorrhage. The liver was enlarged, but the spleen was not felt. The temperature was 102° F. There was no "typhoid" condition, but the patient was obviously extremely ill with slight delirium.

The history was that on March 29th she had had a slight shivering fit, with backache, and gradually her legs felt heavy. Her tongue was ulcerated; and she had been vomiting and coughing up mucus from time to time. The jaundice was not noticed until the day of admission, but the swelling of the neck and of the parotid had occurred the day before. The haemorrhages had started eight days before admission, in the arms and per anum, and there was increasing pain in the back, arms, and legs, especially in the arms.

Course of the Disease

There was occasional vomiting even after the temperature became normal, which it did in two or three days. There was a gradual improvement, and desquamation became general. There was no objection by the patient to taking fats or eggs, and the digestive processes were all normal. The patient steadily recovered, leaving the hospital on May 8th. On May 16th she was convalescing with still a little trace of jaundice and faint haemorrhagic stains in the skin, and the weakness that would follow an illness of some duration. She is now (May 28th) practically well. There was no relapse. Since the symptoms appeared to point to Weil's disease, pathological examinations were made, and *Leptospira icterohaemorrhagiae* were found in the urine on three separate occasions.

In trying to trace the cause of this isolated and unusual case, it was ascertained that no animals were kept in the house, and that no rats or mice were known to exist there. There was no history of any bite from a rat or other animal, and the other causes of jaundice were excluded. The girl was healthy and enjoyed a normal life. The disease resembled the numerous cases of Weil's disease that have occurred in Holland in the last few years, particularly in Amsterdam and in Dordrecht, in which the patients had been for the most part bathing in the canals. Shortly before the onset of the illness, the patient had eaten "Dutch" tomatoes. The recorded cases in this country are very few and far between.

The patient was not given any specific treatment, as she began steadily to improve from the date of admission to the hospital. After the temperature had become normal she seemed especially to improve on a tonic which contained strychnine and nitro-hydrochloric acid.

Bacteriological Notes

Microscopical.—On three separate occasions, the first on the fourteenth day, the urine was examined for spirochaetes, and these were found. The specimens were centrifuged, and the deposit examined under dark-ground illumination, and also stained by Fontana's silver method. It was found necessary to obtain a very fresh specimen in order to observe the movements, which consisted of rotation and undulation. In stained preparations the spirochaetes were not very numerous, but about a dozen or so of these were seen, and one (the first) preparation was photographed. There was a distinct hook-like tendency at the termination of the spirochaete, but the textbook well-marked hooking was only obvious in a few specimens. It must be remembered that the urine has an action on the morphological appearances, and tends to make the organism appear somewhat atypical.

Biological.—Rather late in the disease animal inoculation of the centrifuged deposit was tried, and a guinea-pig was injected intraperitoneally. No effects were observed, the animal being killed a fortnight after injection.

A. D. Gardner¹ states that the organism occurs both in fresh and in sea water, and can be cultivated therefrom.

Dr. R. A. O'Brien very kindly consented to test to serological agglutination against the leptospira with a specimen of the patient's serum, but suitable strains are not for the moment available.

PULMONARY TUBERCULOSIS AFTER SUNBATHS

BY

A. HOPE GOSSE, M.D.CANTAB., F.R.C.P.LOND.

PHYSICIAN TO THE BROMPTON HOSPITAL FOR DISEASES OF THE CHEST

AND

G. S. ERWIN, M.B., CH.B. N.Z.

ASSISTANT RESIDENT MEDICAL OFFICER, BROMPTON HOSPITAL

The decline in the annual death rate from tuberculosis of the lungs has been so steady since 1860, apart from the war years, that this disease may reasonably be expected to be rare in twenty or thirty years. While therapeutics have helped, the main cause of this magnificent improvement is to be found in the amelioration of social conditions and the education of the patients and the public in preventive measures. The relation of any change in social customs to the development of tuberculosis should be carefully watched. Towards the end of the hot summer of 1933 there appeared in our wards patients with recently developed pulmonary tuberculosis, who were heavily tanned from sunbathing. We therefore decided to make a clinical study of the relation, if any, between this hobby of sunbathers and this disease of the lungs, and we here present the results and some conclusions.

Careful inquiry in each case elicited the fact that out of sixty-six cases of pulmonary tuberculosis admitted under our care between August and December, 1933, the onset, or exacerbation, of symptoms in eleven cases followed sunbathing. Brief histories of these cases are appended, and a study of them shows that there are certain points of similarity in the development of symptoms.

Case Notes

Case 1.—A male, aged 33, admitted August 30th, 1933. In spite of night sweats in January for two weeks, he sunbathed in July. Three weeks later he noticed a cough and felt weak. Sputum positive, x ray positive, on admission.

Case 2.—A male, aged 19, admitted September 13th, 1933. Had haemoptysis in April, 1933. In the following June he sunbathed for one whole day; felt dizzy and lost appetite for two weeks. Sputum positive, x ray positive, on admission.

Case 3.—A man, aged 29, admitted September 20th, 1933. Pneumonia last year; no residual cough. Cough commenced in August, 1933, with one haemoptysis. Sputum positive. In spite of this he sunbathed at Margate for a week, but felt dizzy and sweated at night. Sputum positive, x ray positive, on admission.

Case 4.—A female, aged 20, admitted September 20th, 1933. Quite well and sunbathed during week-ends until, on August Bank Holiday, after sunbathing at Folkestone, felt short of breath and ill for the next few days. Haemoptysis ten days later, then cough developed. Sputum none, x ray positive, on admission.

Case 5.—A female, aged 25, admitted September 28th, 1933. Influenza three previous winters. Quite well till she sunbathed at Broadstairs for one week in June, and on one day had a "bilious" attack, which was attributed to excess of sunbathing. Six weeks later developed a cough. Sputum positive, x ray positive, on admission.

Case 6.—A female, aged 19, admitted November 1st, 1933. Pneumonia in January, 1933. Quite well when she sunbathed at Margate for a week in July, 1933, and felt no ill effects. In September and October dyspnoea. Sputum negative, x ray positive, on admission.

Case 7.—A male, aged 20, admitted November 3rd, 1933. Quite well while he extensively sunbathed at his home and for a week at Westcliff in August, 1933. Haemoptysis in October, 1933, first symptom. Sputum negative, x ray positive, on admission.

Case 8.—A woman, aged 26, admitted November 13th, 1933. In spite of a cough sunbathed for one week early in September, 1933. Did not feel well all the week. Five weeks later, blood-stained sputum. Sputum positive, x ray positive, on admission.

Case 9.—A female, aged 20, admitted November 22nd, 1933. Dry pleurisy 1932; cough persisted. Sunbathed on the river during the week-ends all through the summer of 1933. Haemoptysis in November, 1933. Sputum positive, x ray positive, on admission.

Case 10.—A female, aged 23, admitted December 13th, 1933. Cough since August, 1933. Sunbathed in August for one week. No ill effects at the time. Sputum positive, x ray positive, on admission.

Case 11.—A male, aged 24, admitted December 30th, 1933. Slight cough last winter. Quite well in July, 1933, when he sunbathed for a quarter of an hour each day. No ill effects noticed. Had haemoptysis in November, 1933. Sputum positive, x ray positive, on admission.

The age incidence ranged between 19 and 33, years common to sunbathing and to the production of the exudative type of the disease, which was the one present in all these eleven cases on radiological appearances. On the other hand, although there was a considerable proportion of the fibroid type of disease among the other fifty-five patients, each one of them denied indulging in sunbathing during the summer, and an absence of sun pigmentation supported their statements as far as it could. The fibroid type was present in some patients whose age was greater than the average of sunbathers, and in others who had passed the exudative stage. Many of these patients had a long history of tuberculosis, and had been deliberately warned by their doctors against the danger of sunbathing.

That the abnormal exposure of the usually covered skin surfaces to the action of the sun's rays aggravates the development of pulmonary tuberculosis is a conclusion suggested by these eleven cases and others we

have examined, and we believe this new social custom has elements of danger if indulged in extensively and indiscriminately. This is, of course, in accordance with the known danger of treating apyrexial cases of pulmonary tuberculosis by insolation or carefully graded exposure of the skin to the sun. Years ago it was found by one of us, as by many others who tried it as a therapeutic procedure, that pyrexia and increased activity of the disease sometimes resulted. The danger of artificial sunlight to a patient with tuberculosis of the lungs must also be remembered.

The exact manner in which sunbathing may aggravate tuberculosis is not understood. We do not know whether long sunbaths raise the body temperature in healthy young adults or possibly only in those in a hyper-allergic state. For this latter possibility there is some support in the fact that in our cases several patients showed an immediate reaction in the form of malaise and sweats, as well as a delayed reaction some weeks to three or four months later in the more dramatic form of haemoptysis among other symptoms.

A further point of interest is the fact that our clinical study automatically terminated itself at the end of the year by the non-appearance of new cases with a relevant history of sunbathing. There were none in January or February, 1934. Hence we conclude that the ill effects of sunbathing may be expected to manifest themselves within four or five months of exposure.

Conclusions

In view of our opinion from the experiences gained from this clinical study we venture to draw the following conclusions:

1. It is dangerous for anyone who has had haemoptysis, especially if recent; to sunbathe until tuberculosis of the lungs has been excluded by a thorough examination, including an x-ray examination of the chest.
2. It is inadvisable for people who have recently lost weight, or who are feeling abnormally tired, or who have other suspicious symptoms to sunbathe without the same precautions.
3. Sunbathers who feel tired or feverish, or who perspire at night after a sunbath, should take their temperature, and, if it is above 99° F. in the evening, no more sunbaths should be attempted until they have been passed as fit.

At the June meeting of the Central Midwives Board for England and Wales a letter was read stating that the Minister of Health had approved the existing Rules for a further period of three months from June 30th. A letter was received from the Women Public Health Officers' Association suggesting that, in view of the difficulties experienced by health visitors whose names had been removed from the Roll under Section 3 (2) of the Midwives Act, 1926, in undergoing further training before the restoration of their names, the Board might restore the names on an undertaking being given by the health visitors concerned that they would not practise midwifery without undergoing such further courses of training as the Board deemed necessary. It was agreed to reply that women whose names have been removed from the Roll under Section 3 (2) and who are in actual practice as health visitors be re-enrolled on application and the payment of the restoration fee, and that this instruction should apply to women in practice as health visitors whose names have been removed from the Roll and who would have been ordered further training as a condition precedent to the restoration of their names.

Clinical Memoranda

DRY PLEURISY WITH HIGH EOSINOPHIL LEUCOCYTOSIS

The following is a case of dry pleurisy with a high degree of eosinophilia.

An Indian Christian, aged 21, was admitted to hospital on January 21st, 1933, complaining of cough, low fever, and pain in the chest for one month. He had had cholera in May and heatstroke in June, 1932, but no other previous illness. His trouble had started with a slight attack of cold, passing on to severe spasms of cough, which lasted for half an hour or so and caused breathlessness. At first there was no expectoration; later a thin, white, and slightly frothy sputum was brought up. The fever had reached 100° or 101° F., and was often preceded by rigor. Occasionally he passed into a semi-conscious state, especially after an attack of coughing, accompanied by profuse perspiration. Insomnia was marked.

Physical examination showed, in a thinly built, rather toxic-looking youth, signs of disease at the right pulmonary base—namely, a dull percussion note, diminution of vocal fremitus and resonance and of breath sounds, fine intrapulmonary crepitations, and a loud pleural rub. Elsewhere there were no abnormal signs. Radiological examination revealed infiltration and pleural shadow of the lower part of the right lung; no indication of involvement of the liver could be made out, and the right diaphragm moved fairly even when later there was some swelling of the hepatic region, and the possibility of liver abscess was considered.

The patient's clinical condition varied very little during his three months' stay in hospital, except that the fever became very slight. Pain was most acute, and insomnia very troublesome. He developed dry pleurisy on the left side also, but the signs, radiological and clinical, on both sides gradually cleared up. Needling revealed no fluid, nor was an attempt to relieve the pleural pain, by the induction of artificial pneumothorax, successful. He was given a course of emetine injections on account of the swelling over the liver, and a clinical effect was certainly produced.

So far the probable diagnosis would have been tuberculosis, or possibly amoebiasis, but the pathological examinations introduced a disturbing factor. The sputum was consistently negative for tubercle bacilli and fungi, the blood showed no parasites, and the stools contained no pathogenic organisms. The leucocyte count, however, was abnormal; successive counts were as follows:

Date	Total white blood cells	Eosinophils per cent.
January 21st, 1933	36,800	80
" 27th, "	28,080	78
" 30th, "	35,000	82
February 2nd, "	47,000	79
" 9th, "	51,000	81
" 14th, "	54,000	81
" 25th, "	55,600	83
March 6th, "	108,000	82
" 23rd, "	36,000	77

The eosinophils were both bi- and tri-lobed. The treatment was mainly symptomatic, but, in addition to the emetine, on the possibility of a fungus infection of the lung, large doses of iodide were given for a time, and, on the theory of some allergic condition, auto-blood injections.

Being tired of hospital, the patient was removed by his relations considerably improved, and various indigenous treatments were tried until, in May, he came under the care of the junior author. He was then experiencing every afternoon very severe attacks of cough, followed by thin, frothy sputum, often tinged with blood. After these attacks he passed into a hysterical or semi-comatose condition lasting an hour or two. He was given one dose of 1/2 grain ephedrine hydrochloride, which was followed by an alarming condition of collapse, with a feeble pulse of 140 per minute; from this he recovered after volatile stimulants, bandaging the lower limbs, and raising the foot of the bed. From the next day he was given ephedrine in doses of 1/12 grain four-hourly, and a mixture containing iodide, bromide, and tincture of belladonna. Whenever he experienced a choking sensation he was given a dose of "syrup sourkalp" (a preparation of *Ephedra vulgans*). He was at the same time taking various Ayurvedic

preparations reputed to be useful in chronic lung and debilitating conditions.

As a result of this treatment, combined with careful nursing and feeding, the patient has improved very much. He is now moving about, with no fever, no cough, no pain, and no physical signs, and he has gained sixteen pounds in weight. Radiological examination shows that the lung infiltration has cleared up, leaving simply prominent bronchial markings. The total leucocyte count, however, is still 29,000, with 70 per cent. of eosinophils.

COMMENTS

The cough, pyrexia, pleurisy, and infiltration of the lung strongly suggested a tuberculous cause, and the absence of tubercle bacilli from the sputum did not negative this, but the high degree of eosinophilia could not be reconciled. The possibility of fungus or fluke infection was excluded, so far as repeated sputum examinations could do so. Amoebic infection of the liver with extension to the pleura was seriously considered, and the fact that some benefit followed the administration of emetine gave some support to this, but again it was difficult to account for the eosinophilia; and the leucocytosis, if due to that infection, should have subsided with the treatment. An asthmatic condition did not seem at all likely at first, but the later observations and the final result obtained through ephedrine, iodine, and belladonna, strongly supported the view that it was a case of acute allergic asthma. The infection, as evidenced by the clearing up of the pleurisy and pulmonary infiltration, was an acute but not a tuberculous process. The height of the eosinophilia was the most interesting feature. Reaching 82 per cent. of 109,000, it suggested even an eosinophil leukaemia.

As in the case published in the *Journal* of August 5th, 1933, none of the relations of this patient show eosinophilia. High eosinophilia is a common manifestation of allergic states, and may be the only one. Could the extreme eosinophil leucocytosis in this case be also a rare manifestation of the same allergic state?

University of Lucknow King George's Medical College.

PELVIC CELLULITIS OF UNKNOWN ORIGIN

This case has been reported for two reasons. In the first place it is the only instance known to the writer of pelvic cellulitis of apparently unknown origin, and secondly, it illustrates the imperfection of our knowledge in regard to the aetiology of this type of cellulitis.

A man, aged 45, an inmate of Brentry Colony, who had been in good health, had sudden abdominal pain with vomiting, and a temperature of 101° F., on March 21st, 1934. A flatus tube was passed in vain. Two enemata, one with turpentine, given through a rubber tube as the patient resisted a Higginson syringe, were retained. A small amount of blood was passed per rectum. At midnight the symptoms had not abated, and the enemata could not be siphoned from the rectum. Finding distension in the hypogastrium Dr. Rudolf, medical superintendent, to whom I am indebted for the case, passed a soft rubber catheter easily into the bladder, and withdrew eighteen ounces of normal urine. This was repeated the next day, and thirteen ounces were withdrawn, while a further enema was half returned.

At 2 p.m. I saw the patient at the Bristol Royal Infirmary. He was lying on his side, groaning, and vomiting a brownish fluid, and was obviously ill. The circulation in the extremities was very poor, and they were bluish. The pulse was rapid and small in volume, and the temperature 101.8° F. Clinical examination revealed a dirty tongue but a normal chest. The abdomen was full and rounded; tenderness and rigidity were very marked. A left inguinal hernia, which had been tense,

but yielded to taxis the previous night, felt innocuous. Rectal examination gave no further information. The patient could give very little help in answer to questions, so that the clinical diagnosis of peritonitis from a perforated appendix was somewhat speculative. At immediate operation a right paramedian incision was made below the umbilicus. On reaching the submuscular plane, greenish-black discoloration of the fat was noticeable, but no obvious faecal odour. The extra-peritoneal fat was thickened to half an inch in a sodden, watery state, and was an unusual obstacle to the finding and opening of the peritoneum. Owing to the grave condition of the patient, the operation was finished as soon as a large tube had been inserted in the peritoneum, out of which gushed a brownish fluid with a musty odour. The whole aspect of the case was lethal, and the patient died within a few hours.

The post-mortem findings, for which I have to thank my colleague Dr. A. D. Fraser, revealed a normal peritoneum and contents, apart from a little free fluid. No explanation of the illness was forthcoming from the left inguinal hernia. The whole bladder and adjacent seven inches of the recto-colon were invested in the same rotten greenish-black thickened state of the cellular tissue as revealed by laparotomy. Naturally, possible causes suggested themselves, such as extravasation of urine, etc. However, a detailed inspection of the bladder cavity revealed no trace of leakage, and what odour was present was of a musty character and not that associated with urinary extravasation. The recto-colon was then examined with the same negative results. No visible tear or inflammatory area was visible, nor any sign of mutilation of the skin in that region of the body. No trace of septic or other disease was found in the body.

A. WILFRID ADAMS, M.S.
Senior Assistant Surgeon, Bristol
Royal Infirmary.

A CONVENIENT METHOD OF EXAMINING BLOOD FILMS IN PERNICIOUS ANAEMIA

The comparative diffraction method of estimating the size of red blood corpuscles in cases of pernicious anaemia has frequently been mentioned in the *British Medical Journal*, and it has been noted that elaborate apparatus is not necessary.

One method of observation makes use of the fact that if a steady candle flame is sighted through a film held close to the eye a coloured halo is seen, the size of which varies inversely with the size of the red blood corpuscles. If in front of one eye is held a normal film and in front of the other eye an abnormal film the two haloes are superimposed: if now a voluntary diplopia is produced the images are separated and a comparison can be made as to their size. The muscular effort to produce voluntary diplopia is quickly fatigued, and after a few moments leads to a feeling of giddiness and sense of strain.

The following method, which is not dependent on muscular action, has proved very satisfactory in the author's hands.

The film to be examined is held, with the long axis vertical, by the thumb and second finger of the right hand in front of the right eye, the top of the slide steadied against the eyebrow. The pulp of the first finger of the right hand is placed at the outer margin of the orbit, and diplopia produced by pressure against the eyeball. The standard film is held in front of the left eye. The haloes are produced in the usual way, by sighting a steady candle flame through the two films. In order to avoid error (chiefly from anticipation of the result) it is better to mix the slides, so that the observer does not know which is standard and which anaemic, and then to change over and observe again before noting which slide is which.

The method described is very simple, and allows for a prolonged inspection of the haloes without fatigue. The degree of diplopia can be varied by pressure of the finger, so that the haloes can be entirely separated or partially superimposed—the latter being a useful device when the difference in size is not at once obvious.

G. H. H. BOOTH, B.Sc., M.B., Ch.B.

Reviews

FOUNDATIONS OF SURGERY

The recently published *Textbook of Surgical Anatomy and Physiology*,¹ by NORMAN C. LAKE and C. JENNINGS MARSHALL, is an important addition to surgical literature. The status and experience of the authors as operating surgeons, teachers, and examiners would lead one to expect a work of more than ordinary merit: this expectation has been fully realized. The scope of the book is much more comprehensive than its title would suggest. Its subject-matter ranges over the whole field of surgery and its subsidiary sciences, and a vast amount of information, hitherto only obtainable from a multiplicity of sources, is brought together in a single volume.

The work is divided into two main sections: general and regional. The general section is devoted to a consideration of the principles of anatomy, physiology, and pathology in their broad application to surgical diagnosis and treatment. The chapter on the central nervous system, for example, deals with the general structure and function of the brain and spinal cord, intracranial pressure, examination of the cerebro-spinal fluid, spinal anaesthesia, radiography, and cerebral localization; that on the peripheral nervous system, with the arrangement and structure of the somatic and sympathetic nerves, the results of nerve division, and the phenomena of visceral pain. The descriptions of the fasciae and connective tissues, skin, and subcutaneous tissues make interesting reading: full of important practical observations, they are among the best in the book. The chapter on muscles and tendons contains, at some length, Hunter's theory of muscular control. The general section also includes accounts of the vascular system, bones and joints, serous cavities, and alimentary canal. In the regional section the sequence—development, anatomy, structure, physiology, pathology, operative, and practical applications—is generally followed. Development is given in sufficient detail to enable the student to understand clearly the more important congenital defects. In particular, the account of the development of the urogenital system is exceptionally clear, with admirable diagrams. The addition of a few more diagrams to the descriptions of the development of the serous cavities and diaphragm would increase their value. Systematic descriptive anatomy is presented in a compact, slightly condensed form, near the beginning of each chapter, easily accessible for revision or reference. It is accurate, complete, and well illustrated. There are numerous allusions to comparative anatomy and morphology. The physiology is generally brief, but adequate for the understanding of pathology: in the parts where a fuller treatment is called for, such as the stomach and biliary systems, this is given. Pathology is dealt with systematically and in fair detail.

The special value of the book, however, and that which gives it its peculiar quality, lies in the correlation of these fundamentals with the problems of surgery. This object has been achieved with remarkable success. It is here that the experience of the authors as practising surgeons, and their abilities as teachers, become most evident. The whole aim of the book is practical. A sound sense of proportion is maintained throughout, and the common temptation to devote an undue amount of space to a topic merely because it is a prevailing surgical fashion has been resisted. The important subject of the surgery of the hand, with special reference to infection, receives the large amount of space which it deserves. The chapter on the sympathetic nervous system

is brief but clear, with good diagrams, and contains all that the student needs to know of the subject. The "special" subjects, particularly the eye, are comprehensively treated.

The style of writing is clear and concise—a model of what scientific writing ought to be. The illustrations, of which there are 238, many in colour, are a notable feature. They are well chosen and very clear, and the great majority are original. Many of them are beautifully drawn: in this respect the work of Miss Barclay Smith deserves particular mention. There are a number of misprints in the text and illustrations, and it is to be hoped that more careful proof-reading will remove these in a second edition. Judged by every standard, this is the best English textbook on the subject, and we congratulate its authors on their achievement.

EXPERIMENTAL EMBRYOLOGY

It adds greatly to the pleasure to be gained from a scientific book when the authors have not only an intimate acquaintance with their subject-matter but also a thorough mastery of the technique of writing. Professor JULIAN HUXLEY and Dr. G. R. DE BEER have produced a book on *Experimental Embryology*² which starts, goes on, and finishes, and one of the most valuable chapters is No. XIV, "Summary," which is an admirably lucid essay on what it has all been about.

The problem of the manner in which the animal embryo develops from the fertilized egg is one which has given rise to many a dusty battle among the giants and lesser fry of biology ever since the invention of the microscope led to the discovery of the sex cells. On the one side were ranged the champions of pre-formation, who claimed that embryological development was due to the gradual manifestation of a complex structure already pre-existing in the egg (or even in the sperm), and on the other, the protagonists of epigenesis, who claimed that every embryo arose anew. The present authors have brought under review an immense amount of observational and experimental evidence, gathered from studies in embryology, cytology, physiology, and genetics, as well as from the younger science of experimental biology. Their verdict is best given in their own words:

Animal development is truly epigenetic, in that it involves a real creation of complex organization. It is also pre-determined, but only in the sense that an egg cannot give rise to an organism of a species different from its parent. The development of each individual is unique. It is the result of the interaction of a specific hereditary constitution with its environment. Alterations in either of these will produce alterations in the end-result.

With this verdict the reader must agree, for the book is a monument of reasoned thought and balanced judgement. Not the least impressive part of the evidence is that derived from experiments which involve surgical operations on eggs and embryos so fine that even single cells, or parts of cells, are excised or transplanted. The outstanding facts which modern experimental research has brought to light are the existence of "organizers" and of "gradient fields." Organizers, which are usually localized in a specific region in the early embryo, such as the dorsal lip of the blastopore in amphibian embryos or the primitive streak in avian embryos, have now been shown to be chemical substances, in the former case, at least, probably lipoidal in nature. Unless the organizer is present no embryo will develop, and, conversely, if the organizer is grafted into an abnormal position in the blastula, embryological development will be induced in an abnormal position. Gradient fields are regions in the egg

¹ *Surgical Anatomy and Physiology*. By Norman C. Lake, M.D., M.S., D.Sc., F.R.C.S., and C. Jennings Marshall, M.D., M.S., F.R.C.S. London: H. K. Lewis and Co., Ltd. 1934. (Pp. x + 888; 238 figures. 30s. net.)

² *The Elements of Experimental Embryology*. By Julian S. Huxley, M.A., and G. R. de Beer, M.A., D.Sc. London: Cambridge University Press. 1934. (Pp. 514; 221 figures. 25s. net.)

or the embryo in which there is a gradient of metabolic activity. One, two, or more gradient fields may be present, probably each based on a specific chemical cycle, and these may overlap. Not only does the discovery of organizers and gradient fields account for normal development, but it also shows why anything which dislocates or disrupts the organizer region, or which disturbs the normal gradient, must lead to the production of abnormal or monstrous forms. For instance, the internal asymmetry of the externally symmetrical vertebrate embryo has been shown to be due to a left-to-right gradient of growth rate, the left side growing more actively than the right. Controlled application of cold or other damaging agencies to the left side of the embryo leads to a reversal of the growth gradient and the production of embryos with reversed internal asymmetry.

The authors have ranged far. They have dealt with the significance of nucleus and cytoplasm, restoring to the latter its true value, of which an over-zealous pursuit of genetics has in recent years been inclined to rob it; of the influence of the parts of the embryo on the whole, and vice versa; of the special influence of the nervous system, and of the development of function by the differentiated parts. The problem of the influence of both internal and external environment on development is handled clearly; and to the age-old question whether the organism is the product of its heredity or of its environment the authors answer, very explicitly—of both.

BARBITURATE POISONING

During the past year a great deal has been written about barbiturate poisoning, and hence a recent monograph on this subject, entitled *Acute Barbiturism*,³ has a special topical interest. The authors (Professor CARRIÈRE, Dr. HURIEZ, and M. WILLOQUET) are attached to the Medical School of Lille, and their inquiries show that barbiturates have in recent years become a common method of suicide among French women. They give an excellent summary of the clinical features of the condition, and supplement this with an account of the morbid effects observed in experimental poisoning of animals. The most striking pathological change is an acute tubular nephritis, and this accords with the fact that oliguria and albuminuria are frequently observed in severe clinical cases of poisoning.

Most of the volume is concerned with treatment. In 1932 Haggard and Greenberg showed that dogs could survive two or three times the usual lethal dose of a barbiturate if given strychnine in quantities equivalent to three or four times the usual lethal dose. The results of their work were popularized in France and in Belgium by Professor Ide, who supported this treatment with enthusiasm. Several other very varied methods have also been recommended in recent years—for example, adrenaline, intravenous injections of hypertonic glucose, camphor injections. (An account of these results was published in the *British Medical Journal* of December 16th, 1933, p. 1131.) The authors of the monograph under review studied the barbiturate-strychnine antagonism in animals, and found it only moderately effective. They therefore tried other methods. First, they used injections of coramine (di-ethylamide of pyridine carbonic acid), and found this more successful and less dangerous than strychnine. They next tried the somewhat surprising method of intravenous injections of 30 per cent. alcohol in doses of 1 c.cm. per kilo repeated hourly. This treatment had a remarkable action in cutting short the coma produced by barbiturates. It was tried successfully with a case of poisoning in a human being: the patient received four doses (20 c.cm. each) of 30 per cent. alcohol intravenously.

³ *Le Barbiturisme Aigu et les Antidotismes Garderel*. (Strychnine, Coramine, Alcool) Par G. Carrière, Claude Huriez, et P. Willoquet. Lille. Imp. A. Durant. 1934 (Pp. 164)

The authors conclude that both coramine and intravenous alcohol are superior to strychnine in the treatment of barbiturate poisoning. It must be confessed that the results with alcohol are very surprising, since high concentrations of alcohol in the blood can produce a coma as deep as that produced by poisonous doses of a barbiturate. In view of the frequency of barbiturate poisoning in some countries it is a matter of practical importance to determine the most effective means of treatment. The work recorded in this monograph is very interesting and suggestive, but the experimental results are rather few in number, and it is to be hoped that more extensive inquiries will be made into the comparative value of remedies.

RADIOLOGY OF THE ACCESSORY SINUSES

In a large series of monographs on radiology from the publishing house of Thieme at Leipzig is included an admirable production on the Accessory Sinuses of the Nose and the Ear by Dr. RICHARD MITTERMAIER, from the clinic of Professor Kahler in Freiburg.¹ This is partly a monograph on the technique required to obtain constant and reliable views, and the positions of the head and target required are fully studied and described. The greater portion of the book is really an atlas of radiographs illustrating the anatomy and pathology of these regions as shown in x-ray films taken by the methods described. The reproductions are so good that but little detail has been lost, and the collection of films contains specimens illustrating almost every variety of simple inflammation, suppuration, and tumour formation which is to be found in these situations.

The work should be a good guide to those who have to undertake this special branch of radiology, and a study of it will be of great help to those on whom the responsibility for interpreting these radiographs ultimately rests. It will therefore be quite as valuable to those who practise otology and rhinology as to radiographers.

RECENT ADVANCES IN PATHOLOGY

When reviewing the first edition of *Recent Advances in Pathology*,² by Professor HADFIELD and Dr. L. P. GARROD, we recommended it for its simple, clear, and straightforward accounts of most of the recent work which had not then found its place in textbooks of pathology. The second edition, which is better than the first, but lacks its novelty, contains fifty-five more pages, and there has been some addition to, and rather more rearrangement and rewriting of, the sections.

The main alteration is a new section on the pituitary gland, which had been unaccountably omitted from the first edition. In the same section some account is given of the influence of the adrenal cortex on sodium metabolism and the importance of this in the treatment of Addison's disease. Anaemia is discussed under gastric pathology, and here the authors overstate their case when they say that in gastric cancer "the macrocytic ('pernicious') type of anaemia to be expected from this loss of secretory function is common, and is now known to respond promptly to liver treatment." The chapters on Bright's disease have been revised, and now include descriptions of focal and embolic nephritis. The chapter on vitamins and vitamin deficiencies has been presented afresh as a review of deficiency diseases from the standpoint of their pathology. This is well done, a short

¹ *Die Krankheiten der Nasennebenhöhlen und des Ohres im Röntgenbild*. Von Priv.-Dor. Dr. Med. Richard Mittermaier. Leipzig: G. Thieme. 1934. (Pp. 141; 213 figures. M.25; geb. M.27)

² *Recent Advances in Pathology*. By Geoffrey Hadfield, M.D., F.R.C.P., and Lawrence P. Garrod, M.A., M.D., M.R.C.P. Second edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 457; 69 figures. 15s.)

account of the vitamin being followed by a note on the changes brought about in the body by their insufficient intake. Monocytic leukaemia is dealt with in the chapter on the reticulo-endothelial system, and here the useful suggestion is made that supravital staining should be more generally applied in examining the blood in cases of leukaemia of uncertain type.

The authors have chosen wisely from the mass of available material, and put forward the facts and their interpretation with sufficient dogmatism and clarity to make their book useful to students and practitioners of medicine alike.

THE WORK OF MESMER

In these days, when the influence of the mind on the body is a phrase in every mouth, and when learning and assertion concerning mental processes command more attention than almost any other branch of medical science, few people perhaps pause to inquire what manner of men founded the movement whose ramifications have become so universal. In the age of faith psychological medicine of a kind was a commonplace, but with the growth of physical science the nature and influence of the mind were almost completely forgotten—so much so, that even nowadays a belief in healing by means of "mental" therapy is still viewed with suspicion. The name of one prominent early worker in this field has passed into more than one language in a cant phrase, but little is popularly known of him, even among psychotherapists, beyond that he was a pioneer of the study of animal magnetism.

In her life of Friedrich Anton Mesmer (1733-1815)* Miss GOLDSMITH traces the development of his researches into the new principle through his days at the Jesuit College at Dillingen in Bavaria, where he came in contact with the rationalistic work of Christian Wolff, which gave him scientific method, and with the work of Descartes, who convinced him that men's lives were influenced by movements of the heavenly bodies. He was passionately fond of music, and his marriage to a wealthy woman made him financially independent, though his married life gave him no emotional interest. If he had had no personal claim on posterity he would have deserved highly of it for the indispensable help he gave Mozart in his early days. Mesmer's association with Father Maximilian Hell, a pioneer in the therapeutic use of steel magnets, turned his mind in the direction of other means of using the mysterious "fluidum" in which he believed. He thought that his own body emanated the fluid and that he was able to cure by passes of his own hand. To the end of his life he seems to have rationalized his results in terms of physiology and astrology, without realizing that he was really practising psychotherapy. His astonishing history of miraculous cures led to unpopularity, and he had to leave Vienna for Paris, where he attracted a large following, and at one time attained the standing almost of a prophet. His methods were investigated by a commission of the Academy of Sciences, which, from an entirely materialistic point of view, condemned him. His popularity waned, and he became more and more the butt of satirists, and was finally taken off the Register. Nevertheless he continued, as a layman, to study sleep and somnambulism, and to investigate mental disorder. His disciples disappointed him by developing his ideas along lines with which he did not agree.

Miss Goldsmith's story is as much about the development of Mesmer's theories as about the man, but she shows clearly the connexion between his inspired gropings and the latest developments of psychotherapy. She writes clearly and interestingly, and the large print and handy format of her book should recommend it to many readers.

* *Mesmer: the History of an Idea.* By Margaret Goldsmith. London: Arthur Barker, Ltd. 1934. (Pp. 276. 10s. net.)

Notes on Books

The third edition of *A Text-Book of Medicine*,⁷ by American authors, revised and entirely reset, is the work of over 140 contributors, and is edited by Professor CECIL of Cornell University Medical College. It is a good straightforward textbook, clearly written, full of facts, not overburdened with pathological data, sound, and conservative in the matter of treatment. The book reflects current American practice at its best, and may be warmly recommended to both practitioners and students of medicine. It is well turned out, and has an excellent index.

*Cheap Diets*⁸ contains menus, with ingredients and amounts required, for a week's meals for (a) four men doing light to moderate work, or (b) a family with a man-value of 4 (Cathcart scale). Cost is not given, as that is dependent on too many conditions. The total value for each day's diet is stated, and the average for the week is: proteins 86.3 grams, carbohydrate 426.5 grams, fat 100.5 grams, calcium 1.2 grams, phosphorus 1.5 grams, and iron 0.013 gram; and calories 3,022. Milk allowed is sufficient to give at least one pint daily to each child under 14; vegetable allowance is high, and these two factors admit of an adequate vitamin as well as mineral supply. The notes on cooking in general, and the recipes for dishes, are practical and easily followed, and the diets are simple enough to be prepared by unskilled workers. The cost should be moderate and the food palatable, while alternative recipes suggest variations. Miss MACKIRDY and Miss ANDROSS have produced a most useful booklet, the small price of which permits of its being in the hands of housewives with very modest means.

SCHUNTERMANN's book on Inflammation of the Lungs⁹ gives the reader a very full account of pneumococcal pneumonia in all its aspects, more than a third of its pages being devoted to treatment. It is well written, with full discussions of the many disputed or doubtful points on which decisions must be made by those who are responsible for the treatment of patients with pneumonia; the author states that the vaccine treatment of the disease finds few supporters in Germany. The book may be strongly recommended to all practitioners of medicine who can read German.

The treatment of tuberculosis of the lungs and of other parts of the body by the hydrotherapeutic and climatic resources of France (including Corsica and Algiers) is described by BERNARD and EVEN in their small book on the Hydroclimatic Treatment of Tuberculosis.¹⁰ The technique of the various treatments recommended is described, as are the indications for their employment. The volume should be of service to medical practitioners who have to treat tuberculous patients in France. A second volume by M. PIÉRY¹¹ deals similarly with the treatment of the non-tuberculous diseases of the respiratory tract, and may be recommended in the same terms.

A further instalment of the *Collected Papers of the Walter and Eliza Hall Institute of Research in Pathology and Medicine*, Melbourne, of which Dr. C. H. Kellaway is the director, has now been published in a single volume, covering the years 1930 to 1933. These forty-one papers are reprints from various medical journals in Australia and Great Britain.

⁷ *A Text-Book of Medicine.* By American Authors. Edited by Russell L. Cecil, A.B., M.D., Sc.D. Third edition, revised and entirely reset. Philadelphia and London: W. B. Saunders Company. (Pp. 1,664; 30 figures. 42s. net.)

⁸ *Cheap Diets. Representing a Week's Meals.* Compiled by Mary Mackirdy and Mary Andross, B.Sc. Foreword by Professor E. P. Cathcart, M.D., D.Sc., F.R.S. Glasgow: Wm. Collins Sons and Co. Ltd. (6d. net.)

⁹ *Die Lungenerkrankungen.* Von Dr. Med. Carl-Erich Schuntermann. Immunität, Allergie und Infektionskrankheiten, Band iv, Heft 1-3. München: Verlag der Ärzteischen Rundschau Otto Gmelin. 1933. (Pp. 140; 38 figures. R.M.7.50; geb., R.M.9.)

¹⁰ *Thérapeutique Hydro-Climatologique de la Tuberculose.* Par Léon Bernard et Roger Even. Paris: Masson et Cie. 1934. (Pp. 146. 20 fr.)

¹¹ *Thérapeutique Hydro-Climatologique des Maladies non Tuberculeuses de l'Appareil Respiratoire.* Par M. Piéry. Paris: Masson et Cie. 1934. (Pp. 160; 20 figures. 20 fr.)

LONDON HOSPITAL STUDENTS' HOSTEL

OPENING BY THE QUEEN

The new London Hospital Students' Hostel was opened by Her Majesty the Queen on Tuesday last, July 3rd. The Queen, on arrival, was received by the chairman of the hospital, Sir William Goschen, and among those presented were Professor L. N. G. Filon (Vice-Chancellor of the University of London), Dr. Edwin Deller (Principal of the University), Lord Dawson of Penn, Sir E. Graham-Little, M.P., Professor W. Wright (dean of the London Hospital Medical College), Colonel W. M. Pryor (chairman of the College Board), Dr. Cecil Wall (senior physician), Mr. Hugh Lett (senior surgeon), and the Mayor of Stepney (Mr. R. J. Woodham). A guard of honour, made up of the medical section of the University O.T.C., was drawn up in front of the building.

The Queen was presented by the architect, Mr. Edward Maufe, with a ceremonial key, and with this Her Majesty opened the main door, afterwards inspecting the hostel and ascending to the roof garden. After the ceremony she walked through the hospital gardens, visited several of the wards, and before returning to Buckingham Palace took tea in the committee room with the chairman, the matron, and Lord and Lady Dawson.

The new building, which is close to the hospital, is a noteworthy addition to East End architecture, and brings a grace and modernity to the London Hospital site which no part of the older fabric can claim. Its architectural distinction is such that a drawing of it is hung "on the line" in the present exhibition of the Royal Academy. A feature of the frontage is the handsome colonnade, supporting a balcony to which access is obtained from the first floor. There are bay trees at each end of the balcony, and over the central window there is a touch of colour in the shape of the crest of the London Hospital worked in the stone.

On the four upper floors residential accommodation is provided for fifty-two students, a bed-sitting room for each, very neatly furnished, with double sets for the warden, matron, and senior students. The ground floor contains the dining room, the common room (the furniture of which includes a grand piano), the library, and a small writing room. The dining room and common room, divided by the central hall, run the whole length of the main front. The library is to be named the Knutsford Library, as some acknowledgement of the provision from the Knutsford Remembrance Fund of a contribution of £3,000 towards the hostel. A large painted portrait of Lord Knutsford appears above the fireplace. A feature of both the library and the writing room is the wall illumination; both rooms look out on an internal court. In the basement is ample storage room for luggage. The two side wings of the building are finished with roof gardens, and on the main roof are two standard squash

racket courts with a gallery between them. The external walling of the building is in brown-red brick with wide joints; the cornices and window surrounds are of reconstructed stone, and the glass of the windows is set out in front of the walling. The hostel, which is on an open site, looks out on to Philpot Street in the rear of the hospital, and is only a minute's walk away from the Medical College.

The first active steps towards the erection of a students' hostel for the "London" were taken nearly four years ago. The need for such a building was so urgent that it was felt that a determined effort should be made to collect the money required, in spite of the fact that the economic depression was already casting its shadows before. Ultimately £15,000 was collected and the building was started, but

a further sum of £17,000 is necessary in order to free the hostel of debt. The Hostel Committee, with Mr. Hugh Lett as its chairman, has issued an appeal for the reduction of this debt, for if the debt remains, involving heavy interest charges, it will seriously deplete the resources of the hostel and necessitate a higher charge for residence than had been contemplated. It is hoped to make the charge for the rooms such as is within the means of the students generally,

and even to give special concessions in deserving cases.

LONDON HOSPITAL MEDICAL COLLEGE STUDENTS' HOSTEL

The July number of the *Practitioner* is largely devoted to neurological subjects. It opens with a paper on some common "functional" disorders by Dr. Edwin Bramwell, who is followed by Professor Arthur Hall on the prognosis and treatment of chronic epidemic encephalitis, and by Dr. James Collier on epilepsy and its treatment. Dr. Macdonald Critchley discusses the mechanism and treatment of migraine, Dr. Anthony Feiling writes on hemiplegia, and Dr. O. H. Gotch on paraplegia. Dr. Robert Lees contributes an article on the treatment of syphilis of the nervous system, based on the papers and work of his uncle, the late Dr. David Lees of Edinburgh. Mr. L. R. Broster writes on concussion and its treatment, and Dr. J. St. C. Elkington on the significance of wasting of the upper extremity in nervous diseases.

Dr. J. R. Yung, corresponding secretary and president-elect of the American Association for the Study of Goiter, writes to inform us of the award of the Van Meter prize of 300 dollars for the best essay written on the subject of goitre, especially its basic cause. Essays were received from England, Germany, Switzerland, Italy, Canada, Austria, Hungary, and the United States. The prize has been awarded to M. A. B. Brazier, Ph.D., B.Sc., the Maudsley Hospital, London, for "The Impedance Angle Test for Thyrotoxicosis." First honourable mention is awarded to Professor Ugo Cerletti of the University of Genoa, Italy, for his essay, "Three Years of Experimental Research in the Aetiology of Endemic Goitre"; and second honourable mention to D. Roy McCullagh, M.D., of the Cleveland Clinic Foundation, for "Studies in Blood Iodine using a New Chemical Method."

ONE HUNDRED AND SECOND ANNUAL MEETING
of the
British Medical Association
BOURNEMOUTH, 1934

THE one hundred and second Annual Meeting of the British Medical Association will be held in Bournemouth this month, under the presidency of Dr. S. Watson Smith, who delivers his address to the Association on the evening of Tuesday, July 24th, in the Pavilion concert hall. The sectional Meetings for scientific and clinical work will be held on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th, the morning sessions being given up to discussions and the reading of papers, and the afternoon to demonstrations. The Annual Representative Meeting for the transaction of medico-political business will begin on the previous Friday, July 20th. The full list of presidents, vice-presidents, and honorary secretaries of the sixteen Scientific Sections, together with the provisional time-table and programme, was published in the *Supplement* of June 16th. Other details of the arrangements for the Annual Meeting will appear in subsequent issues. We publish below the fourth of a series of descriptive and historical articles written for the occasion. The first, on Bournemouth and its attractions, appeared on January 6th (p. 22); the second, on the hospitals, etc., on March 3rd (p. 391); and the third, on some geological and archaeological features, on May 5th (p. 814).

THE NEIGHBOURHOOD OF BOURNEMOUTH

Than Bournemouth there can be few places in the British Isles more perfectly set and naturally beautiful. Both within the boundaries of the town and on the outskirts are numerous beauty spots and viewpoints which command landscapes that, of a sudden, break upon the eye in their surprising magnificence, embracing as they do vast stretches of coast line, cliffs and coves, woods and heath, and hills. From Hengistbury Head (now scheduled as an ancient monument) can be viewed at one sweep the Isle of Wight, the Solent, Highcliffe, Christchurch, and the whole of the Bournemouth Bay as far as the Old Harry Rock near Swanage; from the East Cliff and Canford Cliffs can be seen at one stretch the bay from the Needles to Old Harry; and, most splendid of all, the panoramic view from Constitution Hill, Parkstone, of Sandbanks, Brownsea Island, the lakeland of Dorset, the Purbeck Hills, and many miles into the county of Dorset—the view the splendour of which so startled King Edward VII when he drove out on to the summit of the hill there.

Bournemouth forms a good base from which to visit the adjacent parts of Hampshire and Dorset. This city by the sea has been described as the gateway to a realm of historic interest and scenic beauty. From the Square roads run fanwise into the two counties, and give ready access to every hamlet and point of interest. Each place visited has a history and an attraction of its own. Even the trip to Sandbanks by way of Branksome Avenue and Chine and through the pine woods of Canford Cliffs has its delightful surprise as the top of the hill is reached in the view of Brownsea Island, Poole Harbour, and Sandbanks itself, which forms the eastern promontory enclosing the harbour.

At Sandbanks a chain ferry takes passengers and vehicles across the narrow channel to Shell Bay and Studland along the shorter road to Swanage. The longer route passes through the ancient seaport town of Poole, an old Roman station on the Via Iceniana, where Alfred the Great is said to have built his ships, and curves on through Lytchett Minster, where the inn displays a sign showing St. Peter holding up a bleeding hand—a corruption of St. Peter ad Vincula, one of the days under the old feudal land tenure when predial service was done for the lord of the manor. The approach road to the Roman town of Wareham bridges the Frome, and brings into view the ancient earthworks outside the present borough

boundaries. Below Wareham the river, which runs down into the Dorset lakeland, is still navigable by yachts and small vessels. In the Church of St. Mary here King Edward the Martyr, who was stabbed and killed at Corfe Castle, was buried; three years after, his casket was disinterred and his body removed to find its last resting-place in Shaftesbury Abbey.

From Wareham the road to Swanage passes over bleak and at times forbidding moorland, passing close by Corfe Castle, now a magnificent ruin, and on through the old-world village of Corfe. The Purbeck Hills now come into view on the right. From the Swanage cliffs are seen on the east the Old Harry Rock, and on the west Durlston Head, St. Aldhelm's Head, and the majestic white cliffs of the Dorset coast. At Worth Matravers Benjamin Jesty of Downshay, who anticipated Jenner's experiment by two years, is buried; Jesty inoculated his wife and two sons with cow-pox. The inscription on his gravestone is as follows:

"He was born at Yetminster in this county and was an upright honest man: particularly noted for having been the first person (known) that introduced the cow-pox by inoculation and who from his great strength of mind made the experiment from the cow on his wife and two sons in the year 1774."

Further west are Kimmeridge Bay; Warbarrow Bay, where from the promontory on its east side are to be had glorious views of the Dorset coast, the Purbeck Hills, and on the south-west Portland Bill; and Lulworth Cove.

THE HARDY COUNTRY

Returning to Wareham and thence to Wool, we find the manor house of the D'Urbervilles, the scene of the memorable wedding night of Tess and Angel Clare of Hardy's *Tess of the D'Urbervilles*. Close by is Binden Abbey, and in the grounds is the stone coffin where Tess rested. If on another occasion Dorchester be the objective, a winding country road between hedges and past typical Dorset farmsteads carries one to Bere Regis, a village of thatched houses and a one-time royal seat, situated on a hillside commanding extensive views towards the Purbeck Hills and the coast. Bere is the "Kingsbere" of Hardy's novels, and the canopied tomb of the D'Urberville family is to be seen in the church. Woodbury Fair, held each year in September, is mentioned in

Far from the Madding Crowd; this fair draws visitors from far and near. King John probably made many visits to Bere when he came to hunt in the royal forest of Purbeck. Out of Bere the road forks to the right in the direction of Milton Abbas, the centre of some of the most charming country in England. Milton Abbey, which was built by King Athelstan and was recently purchased by the Ecclesiastical Commissioners, has only to be seen to be admired.

Returning to the main Dorchester Road Puddletown is reached, where there is a glorious relic of ancient Dorset—Athenhampton Hall, one of the many lovely old Dorset manor houses. The church is one of the few in the county which have escaped the restorer. The old oak pews still remain; the ceiling panelling is of Spanish chestnut; and there is a very fine singing gallery, a Norman font, and an old wood pulpit with a clerk's stall beneath. Dorchester itself, the county town of Dorset, was of considerable importance in Roman times. It has four main thoroughfares, and takes a cruciform shape. It is noted for its beautiful avenues and walks. Here are the most noted earthworks in England: the Roman amphitheatre near by Poundbury Encampment, Maumbury Rings, and Maiden Castle. In 1685 Judge Jeffreys, at the Bloody Assizes, sentenced 300 adherents of Monmouth to various punishments; most of them were hanged. Outside St. Peter's Church is a bronze statue of Barnes the poet. Dorchester is the "Casterbridge" of Hardy, who lived at Max Gate, a mile outside the town. Wynford Eagle, a few miles beyond Dorchester, was the birthplace of Thomas Sydenham (1624-89), the "Father of British Medicine"; and in 1598, at Rampisham, was born Francis Glisson, an original Fellow of the Royal Society, and the author of *De Hepate*.

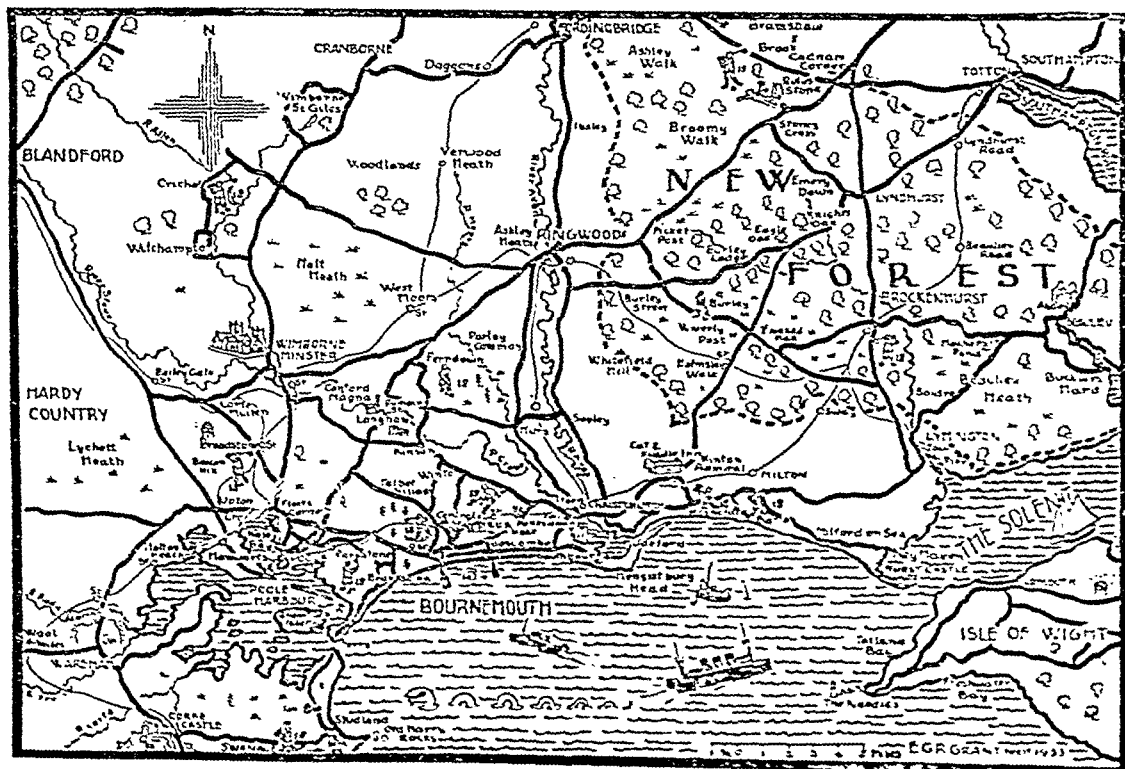

Another very delightful drive from Bournemouth is by way of the old market town of Wimborne. The Minster here is very ancient, and has a chained library of books, at the moment being renovated, of 243 volumes. In the Minster Tower is a quaint astronomical clock constructed during the fourteenth century by a monk of Glastonbury. A nun was first founder of the Minster, Edward the Confessor being second founder. On the grounds that the

Minster was once a "Royal Peculiar," the choirboys wear scarlet cassocks.

On the Blandford Road out of Wimborne, along the avenue of magnificent beech trees, is Badbury Rings, the camp which is situated on high ground (327 feet) and commands views to the sea and for many miles in all other directions. A fine example of an ancient British stronghold, the encampment is formed of a triple vallum and fosse, the area enclosing some eighteen acres. Probably the camp was occupied in turn by Romans and Saxons. At Witchampton some interesting Roman remains have recently been unearthed. Taking the road towards Cranborne, Woodlands is reached, where, after his defeat at Sedgemoor, the Duke of Monmouth was captured. The Duke's pursuers found him hidden by ferns and bracken under an ash tree, still pointed out as "Monmouth's ash." Cranborne is an ancient market town where in 980 a Benedictine priory was established by Aylward de Meux. Some years ago certain paintings, centuries old, were uncovered on the south wall of the church, where also a Norman doorway was found and restored; the old communion plate is of very beautifully wrought and beaten silver. The Manor House at Cranborne dates from the twelfth century. Cranborne Chase was described by Hardy as "a truly venerable tract of forest land, of undoubted primeval date," and is famous in history as a royal hunting forest.

If the road is taken eastwards out of Bournemouth the Stour is crossed and Christchurch reached. The magnificent Priory Church here is one of the finest in the country, and has examples of successive schools of architecture from the Norman to the Renaissance. Near to the church are the ruins of the Castle and a Norman house. The town lies at the junction of two salmon rivers, the Avon and Stour, which here unite to form the harbour, where there is a double tide. The view from St. Catherine's Hill (160 feet) behind the town embraces the Avon Valley, from Christchurch Harbour to the spire of Salisbury Cathedral.

Crossing the Avon by the two ancient bridges, the road to Ringwood passes by Mudeford, an old seaside resort which has seen better days: where at "Gundimere"

Drawn and Published by Dr. E. G. R. Grant.

lived Rose, who translated Ariosto, and where he entertained Sir Walter Scott, who wrote a part of *Marmion* there. Rose also entertained Coleridge at "Gundimore." The road to Ringwood passes Sopley and the sleepy village of Avon, where is pointed out the smithy at which Tyrrel, fleeing after the death of Rufus in the New Forest, had his horse's shoes reversed, then forded the Avon in his flight. Passing on through woods and villages of thatched houses, Ringwood, named "Rincevede" in Domesday Book, is reached. The town lies in a beautiful valley. Monmouth, taken prisoner, lay a night here; and it was here that he wrote his letter to the Queen appealing to her to intercede for his life with the King.

From Ringwood to Fordingbridge the roadway runs through lovely scenery along the valley by gentle Avon and between well-trimmed hedges and past thatched cottages, with nearing hills on each side, giving a vivid and lasting impression of the real beauty of rural England. Here at Fordingbridge Dr. Nathaniel Highmore, who discovered the maxillary antrum, was born (1613). At Braemore, three miles north along the Salisbury Road, is a pre-Conquest church of date A.D. 950-1000, one of the largest and most complete in England. Off the road to Fordingbridge is Ellingham, where there is an early English church, and in the churchyard, near the south wall, is the tomb of the venerable Dame Alicia Lisle, who, at the age of 70, was arraigned for high treason at Winchester before Judge Jeffreys. She was the first and noblest victim of the Bloody Assize (1685), and was condemned by him to "be burned alive until you be dead" that same afternoon. This savage sentence was commuted by the King to one of beheading. Dame Alicia's only "crime" was that at her house, Moyle's Court, she unwittingly gave shelter to two fugitives from Sedgemoor. Close to Moyle's Court is the finest oak in the district; it measures 20½ feet at four inches from the ground.

THE NEW FOREST COUNTRY

If the return journey is made via Gorley, the road runs along the edge of the New Forest in most charming scenery, by fords over two streams, and takes one to Burley, a village lying in a hollow in a clump of trees in the heart of the forest, where some care must be taken to avoid collision with pigs in pannage-time! Thence the road crosses the moor to join the main Southampton Road, which can be followed to Lyndhurst, the capital of the New Forest. Drivers on the roads here need caution because of straying forest ponies: In the Church of St. Michael at Lyndhurst there is the large fresco of the "Ten Virgins" painted by the late Lord Leighton. The King's House (1634), from which the forest is administered, was formerly the residence of the Lord Warden. In the Verderers' Hall (1388), close by, the Forest Court is held every forty days, and the stirrup said to have been used by Rufus the day he was killed hangs over the fireplace. The forest itself covers about 90,000 acres, and measures in length about twenty miles. The greater part is public land. It comprises woods, marshlands, moors, and glades. There is a variety of trees, chiefly oak, with yew, fir, ash, silver birch, wild rose, cherry, elder, hazel, and also gorse, heather, and bracken. Wild flowers and ferns abound. The old gnarled oaks, and the peaceful sequestered glades where the grass grows green, have a beauty all their own. Forest ponies roam at will, but seldom far from their usual haunts. Otters are numerous, and there are a few fallow deer in the forest, and fewer red deer. The timber being no longer needed for men-of-war, the forest has been left in its natural state. Rufus Stone, near Stoney Cross, is well worth visiting; tradition has it that here William Rufus the inelegant, of the red hair and complexion, was accidentally slain by a deflected arrow aimed at a stag by his hunting companion, Walter Tyrrel. At Minstead Church, which is easily visited by way of Lyndhurst Road, is a characteristic old forest church with a three-tier pulpit, two west galleries, and two squire's pews, one having a fireplace. The north doorway is thirteenth century, and inside the church is some fine panelling erected to the memory of Matthews Duncan.

From Lyndhurst to Beaulieu is a run through the forest proper to the beautifully situated village at the head of the winding estuary of the Beaulieu River. About 1204 King John founded a Cistercian abbey here, which in 1327 was endowed by Innocent III with special rights of sanctuary. In 1471, after Barnet, Margaret of Anjou took refuge in the Abbey, and in 1497 Perkin Warbeck took sanctuary there. The Abbey was dissolved about 1538-40. The foundations of the first church are outlined on the turf, the ground plan showing the longest Cistercian church in England (336 feet). The refectory is still used as the Parish Church. Buckler's Hard, on the west bank of the Beaulieu River, is a peaceful village of one broad street, lined on each side by old red-brick cottages. Down this roadway to the waterside were drawn the oak trees for shipbuilding; and here were built and launched forty-four men-of-war, three of which were used at the battle of Trafalgar.

The road back to Bournemouth takes one through Lymington of ancient lineage, which in the fourteenth century contributed as many ships for the invasion of France as did Portsmouth. At Buckland Rings, north of the town, is an ancient British camp. East of Milford-on-Sea can be seen Hurst Castle, one of the line of block-houses built in 1535 by Henry VIII for the defence of the south coast against the French. Here Charles I was brought prisoner from the Isle of Wight, and held until his abrupt removal to Windsor on December 19th, 1648. It is interesting that, after his execution on January 30th, 1649, all editions of the Book of Common Prayer contained a special service for January 30th, the day of execution, as an "anniversary day of fasting and humiliation to implore the Mercy of God."

Returning homewards we pass Chewton Glen, the haunt in spring of the nightingale, the village of Highcliffe, and Christchurch. To those who wish to leave the highways there are many circuitous byways and paths in both counties which lead to sequestered places, "the world forgetting, by the world forgot"; to ancient churches, each with its venerable yew tree in the churchyard, so placed because poisonous to cattle, and in olden days pollarded for bows; to exquisite old manor houses, each with its mulberry tree; and to nearby clusters of ancient homesteads, many with mud walls and thatched roofs, and with little old-world gardens, where, in the words of Galsworthy: "Every blade of grass and flower has a kind of pride about it; knows it will be cared for; and all the roads, trees, and cottages seem to be certain that they will live for ever."

S. W. S.

The following medical promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem are announced in the *London Gazette* of June 26th: As Knights of Justice—Lord Moynihan, K.C.M.G., F.R.C.S., and A. M. Ware, M.D.; as Knights of Grace—the Hon. James H. King, M.D., late Minister of Pensions and Public Health for Canada, the Hon. Herbert A. Bruce, M.D., F.R.C.S., Lieut.-Governor of Ontario, the Hon. Hugh E. Munroe, O.B.E., M.D., Lieut.-Governor of Saskatchewan, and Sir Frederick Menzies, K.B.E., M.D.; as Commanders—A. T. Lakin, M.B., Captain R. J. Isaac, L.R.C.P. and S., Colonel J. T. Clarke, C.B.E., M.C., M.D., R. E. Wodehouse, O.B.E., M.D., Lord Horder, K.C.V.O., M.D., and William Hutton, L.R.C.P. and S.; as Officers—F. B. G. Holmes, M.B., H. E. Gibbs, M.D., F.R.C.S., C. H. Tewsley, M.D., F.R.C.S., Major-General R. B. Ainsworth, O.B.E., D.S.O., K.H.P., Colonel R. C. Wilmot, R.A.M.C., W. D. Kirkwood, M.D., Colonel H. V. Prynne, C.B.E., D.S.O., F.R.C.S., George Thornton, M.D., C. H. Francis-Williams, M.R.C.S., P. R. Bolus, M.B., G. B. Peat, M.D., Major William Nunan, M.D., R. L. E. Downer, M.D., Arthur Heys, M.B., F.O.B. Ellison, M.D., W. N. West-Watson, M.D., and Mrs. Phyllis P. Pigott, M.B.; as Associate Officer—D. H. Mehta, C.I.E.; as Serving Brothers—H. J. Slane, M.D., G. Ll. Pierce, L.R.C.P. and S., S. B. Turner, M.R.C.S., and E. P. Dickinson, M.D.,

British Medical Journal

SATURDAY, JULY 7th, 1934

SCOTTISH HEALTH SERVICES

For a number of years the British Medical Association has been sedulously and continuously engaged in formulating a policy which would provide a complete and unified national health service. A hospital service, a Poor Law service, a public health preventive service, a national health insurance service, have been established in this country in that order over a period of centuries, but almost wholly independent of one another in purpose, finance, and administration. Together they have covered a large part of the field and made the major part of the necessary provision. There are, however, a number of gaps still left in this provision; there is in some directions a great deal of overlapping; there are multiple agencies covering much the same ground, involving much waste of time, effort, and money; and there is a certain detachment or isolation of the various services which is seriously detrimental to the efficiency of them all. The aim of the Association has been to improve the effectiveness of each of these services within its own sphere, to widen some of them so that there shall be no class of the population and no kind of medical help left unprovided for, to minimize the waste of overlapping, to break down the barriers between those working in the several services, and, finally, to co-ordinate and then to unify the machinery and administration of these separate services so that they shall become one organized whole, based upon a well-established foundation, doing no undue violence to well-tried methods, and combining to make complete provision for public health in its curative, preventive, and constructive aspects alike.

This policy has been, in its earlier stages, largely successful. The development of hospital provision, usage, and management, with regard both to in-patients and to out-patients, is being gradually—in many areas too gradually—directed along the lines suggested by the Association. The public health services, including the school medical service, have been enhanced in their status and improved in their conditions by the combined efforts of the Association and of the Society of Medical Officers of Health. The national health insurance service has, during the twenty-one years of its working, been transformed by the cordial co-operation of the Insurance Acts Committee of the Association, the Government Departments concerned, and the more enlightened approved societies, from an over-complicated and almost chaotic scheme into one which works relatively smoothly and effectively. The public assistance health provision, both institutional and domiciliary, is now beginning to be improved and reorganized on lines which the Association was the first to advocate; and it is now widely realized that the field of work of the general medical practitioner must be brought into much

closer relation to that of the public health services on the one hand and to the hospital services on the other.

The complete co-operation between all these services has still to be achieved and their unification accomplished. A method of bringing this about and of completing the national health provision was set out five years ago, after much thought, in the British Medical Association's pamphlet, "Proposals for a General Medical Service for the Nation." This was published ostensibly as a contribution to discussion, and comment and criticism were freely invited. The reception of the proposals has been generally very favourable, and a quite recent review of the proposals in the light of the comments which they have provoked, and of legislation which has bearing upon them, has, in the opinion of the Council of the Association, shown that the principles on which they are based still hold good, and that the methods suggested require only slight modification and some amplification. Financial stringency is still too severe to allow of these proposals being immediately carried into effect, and there are a number of difficult questions arising from them which require serious consideration. The next practical step appears to be the calling of a conference of all those bodies which are most concerned with the matter, and the setting up by such a conference of machinery to deal with different aspects of the subject. A strong desire to this effect has been expressed in more than one quarter, and it is hoped that the Ministry of Health may be able to initiate a conference for this purpose at no distant date.

Meanwhile in Scotland movements have been a little more rapid. There the Department of Health has set up a Committee on Scottish Health Services, and has invited the British Medical Association to give evidence before it at the outset of its proceedings. The memorandum of this evidence has been prepared by the Scottish Committee of the Association and approved by the Council. It will be found in this week's *Supplement*. The Scottish Committee deserves congratulations on the result of its labours, and the memorandum may be commended as a very valuable review of the situation as it appears to the medical profession in Scotland. This review and the proposals arising out of it are, of course, entirely consistent with the Association's policy as outlined above, and as described in the various pamphlets issued by the Association on the instruction of the Council or Representative Body. The memorandum sets out the general considerations which have determined the attitude and action of the Association, describes the present position and needs in relation to the several health services, and makes detailed suggestions for meeting the requirements. There is an appendix concerning the Highlands and Islands Medical Service, which is described as "a unique and almost complete medical service for its specified area."

The contents of the Scottish memorandum cannot be summarized, but attention may be drawn to three particular features. It is insisted very effectively that the status of the family doctor and the

standard of his work are of the very first importance, and that in this regard adequate pay without the need for incessant overwork in unfavourable conditions in order to attain it is a prime necessity. Leisure for thought, reading, and renewed hospital experience is imperative. Further, it is pointed out that the relative smallness of the local government areas in Scotland, as compared with England, makes it desirable that, for health purposes, areas of a wider kind should be arranged. Five such regions are proposed. It is possible that one, or perhaps two, of those suggested may be found unduly large, but the proposal will no doubt receive careful consideration. Lastly, the relation of the health services to medical education is touched upon. This is by no means irrelevant; on the contrary, the need for improved education, undergraduate and post-graduate, for the personnel of the service, and the enhanced opportunities that may be afforded by the service for such education, are alike important. It might have been advantageous if the memorandum had referred more specifically than it does to the corresponding relations with medical research. No national health service which does not afford an appropriate place to research can be regarded as complete. The Scottish Committee is giving oral evidence on the basis of the memorandum, and this will allow of such matters receiving further mention.

CHANGES AT CAMBRIDGE

The next academical year at Cambridge will see some important and interesting changes both in the medical curriculum and in the personnel. The generous bequest of the late Mr. Marmaduke Sheild is now at the disposal of the Faculty Board of Medicine, and the first use made of this has been to re-establish a Readership in Pharmacology, which lapsed after the death of Dr. W. E. Dixon in 1931. As the Downing Professorship of Medicine, which had generally been associated with pharmacology, had already lapsed, a subject which had been so successfully fostered by Dr. Dixon was in sore straits, and Dr. Eric Holmes carried on the work almost single-handed under considerable difficulties. Even after he was appointed to a University Lectureship in Biochemistry Dr. Holmes continued to keep the department in being, aided by Dr. G. N. Myers. Now that excellent laboratories have been provided within the new extension of the Physiological Department and Professor E. B. Verney is returning from University College, London, to his old university to take up the Sheild Readership in Pharmacology, we may confidently anticipate a continuance of the high traditions of teaching and research that Dr. Dixon established. Professor H. A. Harris comes to the Chair of Anatomy also from University College. To further the radiological method in the teaching of anatomy, which he had developed so successfully there, the Faculty Board has provided from the Sheild bequest the sum of £2,000 for equipment and a substantial annual grant for maintenance. This is very appropriate, since Mr. Sheild's

special interest in anatomy was shown by his making a studentship in anatomy the first charge on his bequest. It is hoped with the remainder of the available income to do something for medical parasitology.

This splendid gift to medical education is most opportune, for the new curriculum at Cambridge comes into force in October, 1934. After much discussion, a solution has been reached which commanded general approval in the Regent House. The main point is the disappearance of the second M.B. examination. All students intending to proceed to the degree of M.B. must take a tripos, and if that be the Natural Sciences Tripos, and the required standard is reached in anatomy and physiology, there is no further examination in these subjects. Thus an annoying duplication of examinations is abolished. For those who have not taken these subjects or have failed to reach the standard, a qualifying examination will be held in October and in December. As for the other subjects in the old second M.B., organic chemistry is transferred to the first M.B., while pharmacology is dealt with simply by an oral examination, though optional questions in this subject will also appear in the physiology of the tripos. Now that pathology becomes a subject, though not a compulsory one, in the first part of the tripos, and remains a subject in the Final M.B., a special examination in it is held to be no longer necessary. The tripos itself has been modified to include "half-subjects," more limited in scope, but of the same standard as the others. Chemistry, zoology, pathology, and biochemistry are thus designated, though the first two can be taken as half or whole subjects. A candidate must offer three subjects, or else two subjects and two half-subjects. Assuming that all medical students will take anatomy and physiology, an interesting range of half-subjects is available. The syllabus for half-subjects in chemistry and zoology includes those aspects more particularly suitable for students of medicine. Although the tripos can be taken at the end of the second year, the courses are so arranged as to encourage the student to spend three years over it, unless his advisers consider him competent to enter for the second part of the tripos at the end of three or possibly four years.

It will be noted that the principles underlying these alterations are threefold: the avoidance of duplication of examinations, the insistence on an honours standard, and a still further departure from any attempt at making Cambridge a complete school of medicine—as no doubt Sir George Humphry and subsequently Sir G. Sims Woodhead would have preferred. A student can more profitably devote his three years at Cambridge to a thorough training in the pre-clinical sciences. At the same time arrangements are being made for the clinical teachers at Addenbrooke's Hospital to provide illustrations of anatomical and physiological principles from patients, thus bridging the gap between the normal and the abnormal, of which the student is often so conscious on migrating from the laboratories to the wards. Finally, a word should be added concerning the changes in the regulations for the Cambridge M.D.

An erroneous impression seems prevalent on this point. There is no intention to make it harder to become a doctor of medicine. Rather is it intended to meet the difficulties of those in general practice, to whom the compilation of a strictly academic thesis is often a real hardship. A thesis is still required, but the M.D. committee has the power to give a candidate the opportunity of supplementing this by showing good knowledge of the branch of medicine to which his thesis belongs, at an oral and clinical examination. For such candidates the thesis will be regarded merely as establishing a claim thus to be examined. It is hoped in this way that experienced practitioners, who have become out of touch with academic studies, may attain the dignity of the M.D.

WEIL'S DISEASE IN ENGLAND

Weil's disease, or leptospiral jaundice, is regarded as a rarity in human beings in England, though it has been met with in dogs, particularly foxhounds, among which outbreaks have arisen from time to time. Only one human case has been previously recognized in this country—namely, the one described by Dr. Manson-Bahr in 1922—so that it is something of a coincidence that two cases are recorded in our present issue, and that these two should have occurred within a short time of one another, and in places so far apart as Eastbourne and London. The coincidence is perhaps more remarkable in that the London case was admitted to the Tropical Diseases Hospital actually when Professor Schüffner, who has had such an extensive experience of the disease in Holland and had come to London to lecture on the subject, was visiting that institution. The frequency of the disease in Holland, where during the past ten years 452 cases, with a mortality of 10.2 per cent., have been identified, was attributed to the presence of the canals, which are often in a polluted condition and visited by rats. Like Dr. Manson-Bahr's case, in which the disease was contracted as a result of falling into the Thames, the majority of cases in Holland are due to immersion in the canals from accident or for the purpose of bathing.

The apparent immunity of England will be seriously challenged by the revelations contained in Dr. Hamilton Fairley's paper (p. 10), from which it seems clear that not only did the case described by him contract the infection in a London sewer, but that during the past few years there has been a regular series of infections of sewer workers. These cases have occurred chiefly, if not entirely, among those whose duty it is to repair the brickwork, and who consequently are liable to injury of the hands. We understand, however, that cases have also been observed among the flushers. It has long been known that rats are carriers of the causative leptospira of Weil's disease, and in 1922 the late A. C. Stevenson announced that he had found 30 per cent. of a series of London rats infected. Furthermore, it has been shown by Okell that guinea-pigs seem to be more easily infected with leptospira from the kidneys

of rats if a drop of the kidney material is rubbed into a scarification of the skin than if it is inoculated subcutaneously or even intraperitoneally. As the sewers are swarming with rats, the footprints of which can readily be seen on the slimy material covering the bricks above water level, it is easy to understand how this slime, constantly contaminated with the urine of infected rats, can cause Weil's disease if it gains access to scarifications on the hands of those who are working there, particularly of those whose duty it is to break up the old brickwork with hammer and chisel. Investigations in Holland have actually shown that guinea-pigs may contract the infection if they are made to paddle with scarified feet in polluted canal water. Though the sequence of events seems clear in the case of infections in the sewers, it is more difficult to account for the isolated case described from Eastbourne by Drs. Willoughby and Shera (p. 14). No contact with rats or material known to be contaminated by rats could be traced, so that the source of the infecting leptospira has not been determined. It is recognized that water everywhere, including ordinary tap water, harbours leptospira, but though these are unfortunately indistinguishable from the pathogenic forms from rats and from cases of Weil's disease, and may be cultivated under the same conditions, they do not, except on occasions that are so rare that doubt always surrounds the result, give rise to haemorrhagic jaundice when inoculated in guinea-pigs as do the pathogenic forms. It seems unlikely, therefore, that the Eastbourne case is an instance of the common water leptospira becoming pathogenic. It is more probable that infection arose in some undiscovered manner through rat-contaminated material or even possibly from some infected dog. Rats in Eastbourne, as in many other places in England, have been shown to be carriers of leptospira.

Attention having been called to the association of the disease with London sewers it will be of interest to discover whether the cases are to be regarded as representing a limited outbreak like that studied by Gulland and Buchanan a few years ago in coal pits in East Lothian, or whether they have been occurring unrecognized, as seems likely, over many years, perhaps ever since sewers came into existence. It will also be of interest to know whether the London sewers are peculiar in the production of this type of infectious jaundice or whether other large cities in the country have had a similar experience. There is evidently abundant scope for future investigation, particularly from the point of view of prevention, which might take the form of measures directed towards the avoidance of skin scarification and the cleansing and disinfection of the brick surfaces before breaking-up work commences. Whether any form of protective inoculation can be applied future investigations alone will show. In animals a temporary passive immunity can be produced by the inoculation of immune serum, while a more lasting protection can be effected by means of vaccine prepared from the pathogenic leptospira. Immune serum (which is available in this country) is used for the treatment of leptospiral jaundice in dogs, and undoubtedly should

be administered as early as possible in any human case. Nevertheless it must be admitted that its curative value in animals is little manifest unless given during the early days of incubation. Schüffner records an instance of an infection of a laboratory worker as the result of cutting the finger with a broken test tube containing a culture of leptospira. The temperature rose in seven days, and a search for leptospira in the blood was successful. Immune serum was immediately administered, with very satisfactory results. It is important, therefore, that the diagnosis should be established as quickly as possible, a procedure which presents many difficulties. Direct examination of the blood or plasma, before or after centrifuging, by dark-ground illumination, or even the preparation of stained thin or thick films, may occasionally reveal the organisms in the early stages of the disease. At later stages the leptospira may be found in the urine, while they are more certainly recovered by inoculation of guinea-pigs, in which, however, the infection may not be apparent for a week or more. Serological tests have to await the development of immune bodies, and can only be absolutely diagnostic if they show a rising titre on repetition. It would seem, therefore, that in most cases, to be effective, immune serum would have to be administered on clinical grounds alone, especially when, as in the case of sewer workers, there was good reason to suspect infection from rat-contaminated material.

DANGEROUS DRUG TRAFFIC IN EGYPT

T. W. Russell Pasha, the Director of the Central Narcotics Intelligence Bureau for Egypt, and Commandant of the Cairo City Police, in his report for 1933¹ reviews, with justifiable satisfaction, the progress achieved during the last quinquennium. He claims that, as measured by the number of addicts among convicts in the State prisons, "the narcotic menace" to the country has been largely removed. Reports from the villages confirm this conclusion, while the rising prices for heroin and other narcotics indicate the growing scarcity of drugs of addiction. Many gangs of drug traffickers have been tracked down and eliminated, and it is estimated that thereby some 5,000,000 Egyptian pounds have been saved from transfer from the pockets of Egyptians to the bank balances of these nefarious traders. As regards international traffic, while the export of morphine and heroin from Turkey has been checked, large quantities of illicit opium still leave that country, and Bulgaria has been shown to be a considerable producer of illicit heroin. Contraband hashish of Turkish origin fetches good prices in Egypt, while export from Syria has been checked by the energetic action of the French authorities. Traffickers who were caught received condign punishment by fines and imprisonment, but organized smuggling still flourishes in the Levant, and Greece, though not a producing country of any importance, is nevertheless the centre of contraband commerce of considerable dimensions. Russell Pasha shares the apprehension

felt by the Opium Advisory Committee of the League of Nations in regard to the situation in Manchuria. In this territory opium cultivation is extending, under a Government monopoly, the traffic in prepared opium for smoking is being exploited, Persian opium is being imported, and clandestine drug factories will, it is feared, before long be a serious menace not only to the Far East but to the world. Meanwhile Manchuria, detached from China, is outside the purview of the League of Nations, whose Advisory Committee and Opium Board are without information as to what is going on there and are impotent to control the production and distribution of narcotic drugs therein or to regulate their import and export under international conventions.

THE TRAINING OF CRIPPLES

Ever since cripples' hospitals were first established it has been recognized that it is not enough to correct deformities and to alleviate disabilities, but that the vocational training and maintenance of the cripple still remained to be provided for. After training, however, in a large number of cases, the cripple finds himself still handicapped in his efforts to compete with normal people, and to meet the needs of such cases and to provide a permanent home for workers was one of the aims of the founder of the Cripples' College at Alton. The need of such an important ancillary institution had long been felt in Shropshire by the late Sir Robert Jones and by Dame Agnes Hunt, the founder of the open-air cripples' hospital at Baschurch, afterwards removed to Oswestry. A beginning was made in 1927 when the committee of the hospital, on the urgent representations of Dame Agnes, agreed to purchase a country house and grounds near Oswestry and thus to found "The Derwen Cripples' Training College," which is associated with the Shropshire Orthopaedic Hospital and Agnes Hunt Surgical Home, the annual general meeting of which was held at Oswestry on June 21st, under the chairmanship of Sir Watkin Williams Wynn. At this meeting the honorary superintendent, Dame Agnes Hunt, presented the sixth annual report and balance sheet. Since the Derwen Cripples' Training College was started 273 crippled students have been dealt with, of whom 116 are still in training: sixty-one have found employment outside and are still employed. As showing the precarious state of health of even officially "cured" cripples, it may be noted that thirteen have died during training (from causes not stated), while eighteen others had to be transferred to hospitals for further treatment, presumably on account of relapses or recrudescence of disease; fifteen proved unsuitable for training, and yet another fifteen have not been heard of since discharge. The workshops are at present fitted up for boot making and repairing, the making of Thomas splints of all types, celluloid jackets, mattress making and repairing, upholstery and cabinet making and joinery, toy making, tailoring and painting, and sign making. All these activities cost money, and we are not surprised to find on examining the balance sheet that the college is in debt. To an optimist such as Dame Agnes this matters little, and we feel confident that this difficulty will be got over as others have been in the past history of the Shropshire Orthopaedic Hospital.

¹ Egyptian Government, Central Narcotics Intelligence Bureau. Annual Report for 1933. Government Press, Būliq, Cairo. 1934.

AGRANULOCYTOSIS

F. W. Madison and T. L. Squier,¹ who record fourteen cases in patients aged from 20 to 80, state that the increase in the incidence of agranulocytic angina has synchronized with an increase of drugs containing amidopyrine, and especially those containing amidopyrine with a barbiturate. The disease was found to be most frequent in doctors, nurses, and those directly under medical care. In each of the fourteen cases the onset of primary granulocytopenia was directly preceded by the use of amidopyrine alone or in combination with a barbiturate. All the six patients who continued the use of drugs containing amidopyrine died, while of the eight patients who did not continue their use only two died, and both of these in the initial attack. The administration of a single dose of amidopyrine to two patients who had recovered from the acute attack was followed by a rapid and profound fall of the granulocytes. A rabbit given large doses of allyl isopropyl barbituric acid with amidopyrine by mouth showed an abrupt drop in granulocytes and died on the thirtieth day. The authors conclude that amidopyrine alone or in combination with a barbiturate may produce a primary granulocytopenia in sensitive individuals, and that its appearance after the use of such drugs is the result of an allergic or anaphylactoid drug reaction. An investigation into agranulocytosis in children has been carried out by H. Willi,² who has collected thirty-one cases from the literature in patients aged from 3 months to 11 years, of whom twenty-six died and five recovered, and records four personal cases in children aged $1\frac{1}{2}$ to $5\frac{1}{2}$ years, of whom three died and one recovered. He states that agranulocytosis in children differs from that found in adults by the almost constant occurrence of a previous disease, anaemia, and the frequency of a haemorrhagic diathesis. In his own four cases there was a more or less complete disappearance of the granulocytes. One case proved fatal in eighteen hours, with symptoms of fulminating septicaemia. In the other three cases there was a granulocytopenia with a monocytic reaction. In two of them there was also a very severe thrombocytopenic purpura, and an enormous myeloid reaction followed the agranulocytosis. In this condition there is not only severe damage to the function of the bone marrow, but also paralysis of the rest of the systemic defences. It is attributable not so much to the toxicity of the noxious agent as to hypersensitiveness set up by previous sensitization of the system by a bacterial or chemical agent, such as salvarsan or nirvanol.

"MEN IN WHITE"

To a list of recent medical plays, which includes *The Late Christopher Bean*, *The Wind and the Rain*, and *Living Dangerously*, must now be added Mr. Sidney Kingsley's *Men in White*, at the Lyric Theatre. One comes away well pleased with this performance, for it is brilliantly produced, well cast, and well acted, and presents a story much less improbable than most—well told, and possessing definite dramatic value. It is a serious attempt to solve, amongst many problems, that of the promising but impecunious young surgeon whose career has reached the bifurcation leading to general practice and surgical specialism. The scene is

laid exclusively in a London hospital, where George Ferguson, the hero (excellently portrayed by Mr. Robert Douglas), is R.M.O. and assistant to Mr. Braddock (Mr. Lewis Casson), who gives probably the best piece of character acting in the play. The hero's fiancée, the attractive Miss Jill Esmond, daughter of a rich business man, soon realizes the demands which her future husband's career will make upon her domestic life and peace of mind. A disagreement ensues, and George, weary after a typically hard day in the hospital, succumbs to the attractively provocative wiles of the lonely Nurse Denny. The result is a septic abortion, upon which the hero has to operate under spinal anaesthesia, Mr. Braddock, his chief, having rather gruesomely invited the fiancée to witness George's surgical skill on this occasion. The turmoil which results from this incident is conveniently settled by the death of the unfortunate nurse (from pulmonary embolism) and the anticipated happy ending is eventually reached. Throughout the play the characterization is excellent—there is the pompously incompetent physician whose misdiagnosis of a child suffering from insulin shock enables the hero to effect a dramatic cure with glucose; there is the pontifical surgeon, Mr. Braddock, whose singleness of purpose, sound sense, and honesty command our admiration; in an incidental character there is a fine study of a "failure" who has sacrificed a promising specialist career for general practice; while there are also some good delineations of "housemen," sisters, and members of the hospital staff. Medical (and surgical) details are astonishingly accurate throughout the play, and the scene in the operating theatre is very well done. Whatever may be its implied criticisms of the voluntary hospital and of the law relating to abortion, the play states a very good case for the medical profession.

We regret to announce the death, at Wolverhampton, of Mr. Bernard Cridland, F.R.C.S.Ed., within a few days of the Oxford Ophthalmological Congress, over which he presided in 1929-31 and of which he had been honorary secretary for sixteen years.

We regret to announce also the death, on July 3rd, at the age of 82, of Sir James Kingston Fowler, M.D., consulting physician to the Middlesex Hospital and the Brompton Hospital.

The Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of three years. The committee is constituted so as to afford representation to the local authorities concerned with the working of the Blind Persons Act, 1920, and to voluntary associations for the blind, as well as to organized blind workers. The following have been appointed members: Lord Blanesburgh (chairman), Mr. P. M. Evans (vice-chairman), Councillor W. Asbury, Mr. J. W. Black, Dr. Charles W. Brook, Mrs. Montagu Brown, Alderman C. T. Budgett, Mr. E. W. Cemlyn-Jones, Mrs. Kathleen Chambers, Councillor J. A. Clydesdale, Mrs. I. M. Cowley, Sir Ian Fraser, M.P., Dr. S. J. C. Holden, Miss J. L. King, Councillor E. H. Lee, Alderman C. Lucas, Dr. J. Middleton Martin, Mr. G. F. Mowatt, Mr. Ben Purse, Dr. J. M. Ritchie, Mr. W. H. Tate, and Mr. A. H. Whipple. The committee will advise the Minister on matters relating to the care and supervision of the blind, including any question that may be specially referred to it by the Minister. Mr. H. G. Benjamin of the Ministry of Health will act as secretary.

INTERNATIONAL CO-OPERATION ON HEALTH QUESTIONS

Several matters of interest are dealt with in a résumé¹ just issued from the Office International d'Hygiène Publique in Paris on the proceedings at the April-May session of the Permanent Committee of that body, which was attended by the delegates of thirty-nine Governments, under the presidency of Sir George Buchanan. The work, as in previous sessions, concerned in part the settlement or application of international agreements between Governments on health questions and in part a comparison of data on topical questions of epidemiology and hygiene.

PORT SANITATION

In the first of these categories came the question of standard quantities to be recommended in the case of ships being "deratized" by sulphur for the purpose of the International Sanitary Convention of 1926. The committee agreed to a report to be presented to health departments concerned dealing separately with fumigating by burning sulphur, fumigation by mixtures of sulphur and charcoal, sulphur dioxide in cylinders, and the use of the Clayton apparatus. Special attention was given to the allegation that jute sacks or gunny bags loaded in Calcutta had been responsible for the importation of plague into various places on the coast of South America. Suspicions of this method of transmission were supported by circumstantial evidence, but the committee was unable to regard the thesis as fully proven, and recommended its further consideration when additional data are obtained by the Pan-American Sanitary Conference, which will be held at Buenos Aires in November. An opinion was expressed adverse to giving certificates that ships have been effectively cleared of rats when the holds of the ship have not been emptied before the deratization process.

Some agreements between individual countries for facilitating quarantine operations were noted and supported. Among these is a system by which in northern European ports, from Brest to the mouth of the Elbe, including British ports, the port sanitary authorities follow a system of direct communication one with another in regard to infectious diseases on ships. A more important agreement, particularly from the ship-owners' point of view, is that by which a considerable number of countries are now concluding an accord to dispense either with the production of a bill of health or, at least, with the requirement that bills of health should bear visas obtained from their consuls in foreign ports.

RECENT WORK ON YELLOW FEVER

In connexion with the extension of international health regulations to air traffic which has been effected by the Hague International Sanitary Convention for Aerial Navigation, 1933, the committee gave its attention to evidence that on some air routes mosquitos are habitually carried from country to country by aircraft, and decided on a study of the most effective methods of clearing aircraft from these insects. Note was also taken of the progress made in the application of the mouse protection test in regions of Africa to determine whether particular regions show evidence of the existence within recent years of the virus of yellow fever infection. A study was undertaken of the significance in this respect of what are termed "silent areas"—that is, those in which a material proportion of positive results to the mouse protection test are obtained, but in which there has never been evidence of the actual presence of yellow fever. An investigation of the several questions arising out of these findings is being pursued.

The International Agreement of Brussels, 1924, which provides for the treatment of merchant seamen suffering from venereal diseases, received further attention, and a modified form of the international card given to the seaman has been proposed to the signatory Governments. Finally, the committee reverted to a previous decision. The Office International d'Hygiène Publique, 195, Boulevard

that, for the purpose of the Opium Convention of 1925, an exemption should be made for ampoules of sterilized solutions of morphine and atropine containing as maxima 2 per cent. of morphine salt and 0.05 per cent. of atropine salt. It appeared that there was some risk of the use of these preparations as drugs of addiction, even when put up in this way. A further investigation was decided upon.

The second branch of the work of the session needs less notice, since the different contributions on epidemiological and public health subjects will in due course be published in the Monthly Bulletin of the Office International d'Hygiène Publique. Notable among these contributions are reports from the Yellow Fever Commission of the Office based on work in Africa and America, associated with that of the Rockefeller Foundation, on the distribution and transmission of yellow fever, including a discussion of the "silent areas" above mentioned. Recent work on vaccination against yellow fever by attenuated viruses and by the serum of immunized horses was reviewed.

CHOLERA PROPHYLAXIS

The question of the degree of danger presented by the healthy carrier of cholera vibrios, or vibrios allied to them, constantly arises in quarantine practice, and comes repeatedly before the committee. A new stage was reached at the present session. It was announced to be the intention of the Indian Health Service, with the aid of the Indian Research Fund Association, to follow the recommendations pressed at previous sessions, and that a carefully planned scheme of work on typical and atypical vibrios will now be undertaken in suitable areas in India under conditions which permit the bacteriological results and the appearance of clinical cholera to be studied in association. Special attention will in this connexion be given to typing by sugar fermentation and also to the use of sera prepared from a heated antigen, as proposed by Bruce White. The committee had been asked to specify the dosage of cholera vibrios necessary where protection has to be given by a single inoculation. With certain cautions and reservations, it adopted the figure of 8,000 millions as an average dose for this purpose. A proposal to give official recognition to cholera prophylaxis by the administration of vaccine by mouth was rejected.

SOME MISCELLANEOUS ACTIVITIES

An omnibus report presented by the Subcommittee on Small-pox and Vaccination on modern methods of vaccinating and the effects of vaccination was accepted, and will shortly be published. Further contributions were received on neurovaccine, and on dried vaccine, as well as on vaccine virus grown on the allantoic membrane of the incubated hen's egg. The latter included a report by Goodpasture and others, presented by the delegate for the United States, covering some 1,000 vaccinations done with this virus in schools in Tennessee, which yielded normal results and an insertion success of 94 per cent. The committee considered that it remains desirable to destroy lymph from calves which, on post-mortem examination after the collection of lymph, are found to have tuberculous lesions.

Some new epidemiological data regarding the increase of typhus in several countries were supplied; note was taken of the general interest which attaches to the work of Smith, Andrewes, and Laidlaw on the nature of the influenza virus, and arrangements were made for further international studies of the incidence of Weil's disease and leishmaniasis in Europe and along the basin of the Mediterranean. The present distribution of psittacosis shows that the particular preventive measures taken in the several countries affected need to be adjusted to very different circumstances, and that, while there has been a definite gain to European countries by their having acted together in 1931 to prohibit all importation of parrots at their ports, this joint action no longer has the importance which it then possessed. On more general questions of hygiene it may be noted that a report is to be presented on the practice and results of "terminal disinfection" in different countries.

HEALTH VALUES OF THE EAST COAST

CONFERENCE AT CROMER

In its work of appraising the advantages of British watering places, the British Health Resorts Association, after visits south, west, and inland, has turned to the East Coast, and last week-end, under its auspices, a number of well-known members of the medical profession journeyed to Cromer and Sheringham. The local medical profession—with Dr. R. B. Fawkes in charge of the arrangements—and even the profession from a wider area, as far as Norwich and Yarmouth, contributed largely to the success of the visit, and hotels, business firms, and private individuals co-operated in the welcome. The Cromer and Sheringham Urban District Councils arranged official receptions, and visits were paid to the Cromer and District Hospital and other places of professional interest, as well as to some of the lovely gardens, bird sanctuaries, and remains of ancient man of which this unspoiled part of East Anglia can boast. The weather, which figured rather prominently in the discussions, showed in the course of the forty-eight hours how variable, but on the whole how kindly, it can be on the East Coast.

PROGRESS OF THE HEALTH RESORTS ASSOCIATION

In opening the conference Lieut.-Colonel R. H. ELLIOT said that, notwithstanding the difficulties of its first two years of existence, the association had now gained a more secure footing, though it was still not in a financial position to pursue to the extent it desired the ambitious programme of activities which its enterprising secretary, Dr. Alfred Cox, had planned. But it was steadily teaching the medical profession where to look for authentic information, and the leading medical bodies, and the Royal Colleges, the British Medical Association, and the Society of Medical Officers of Health, and the British Spas Federation had sent to its council men whose names were a guarantee of their appreciation of the reliability and importance of the movement.

Lord Meston, president of the association, at a dinner at Cromer, struck the same note. The association was directing itself to the work of assembling and pooling the information obtained at local conferences and by other means, in which work it was enlisting the support of medical bodies and civic authorities. In this way an encyclopaedia of information would be compiled, so that the general practitioner would know where to send a particular patient, or, what was equally important, having regard to his condition or other circumstances, where not to send him. Three things the association had never attempted to do: to "boss" anybody, to poach on the preserves of other organizations, to decry foreign spas. Justice was done to the toast of "Cromer," or rather to that sunlit arc of coast, from Blakeney to Mundesley, with Cromer in the middle, by Professor W. LANGDON BROWN.

Sheringham, not to be outdone in hospitality, gave a luncheon to the visitors, over which Dr. W. J. E. SUMPTER presided. Here Dr. ALFRED COX voiced the objects of the association, saying that there was no reason why health resorts should not be prescribed with as much precision as drugs. Medical men ought to study the peculiarities of the places to which they sent their patients. In the past the health resort movement in this country had been spoiled by exaggerated and unscientific claims, and one of the purposes of the association was to reduce these to their proper proportions. Sir HOLBURN WARING made the suggestion that the whole subject of health resorts and their utilization in medical practice was deserving of more than a brief notice in textbooks or lectures; it called for a regular course of instruction, preferably post-graduate.

SEASIDE RESORTS FOR RESPIRATORY DISEASE

The first of the two main discussions of the conference, presided over by Dr. F. W. BURTON-FANNING, was on the seaside resort in the treatment of respiratory diseases.

Dr. R. A. YOUNG began by quoting a remark of Ellsworth Huntington the American geographer, that the climate of England is nearer the ideal than almost any other, and that the climate on the shores of the North Sea is the best in the world for human health and activity. In helping patients suffering from diseases of the respiratory organs, a pure air of high humidity, relationally free from dust, a fairly equable temperature, and air changed and moved by breezes and winds, all played a beneficial part. Physiologically the increased respiration and the greater loss of heat might lead to improved metabolic changes, greater sense of well-being, and better sleep. At coast resorts under certain protective conditions elderly bronchitics, instead of being immured out and get the benefits of fresh air, warmth, and sun. The psychological effects, too, were not unimportant, for monotony was an outstanding down-grade factor, and "change of air" was more than a phrase. Cases suitable for coast resorts could be described alliteratively as convalescents, chronic cases, children, and, possibly, the cured consumptive. In convalescence after conditions of the upper respiratory tract the seaside had almost magical properties. The Norfolk coast, with its bracing climate, comparatively rain-free, had much to offer to convalescents and those debilitated by disease or exhausted by overwork.

Dr. L. S. T. BURRELL said that change of climate, like any other restorative, should be ordered with care. On the bracing East Coast one type of patient might recover, while another would be rendered more miserable. It was a common mistake to believe that because a place had a reputation for being healthy, therefore it was healthy for everybody. To regard one place as suitable for the consumptive, another for the bronchitic, and a third for the asthmatic would only lead to error. The variability of the English climate was its outstanding advantage. The patient who needed bracing up did better on the East, whilst the elderly bronchitic, as a rule, favoured the West. On comparing foreign resorts with British ones he had been impressed by the fact that those who stayed in this country and enjoyed it did much better as a rule than those who went to foreign spas, though there were exceptions, and the mere psychological effect of going abroad had gained a certain type of patient. To some people who an annual Swiss visit seemed to become as necessary as cocaine to a dope fiend.

Dr. A. J. MORLAND (Mundesley) declared the East Coast to present one of the most healthy climates in the world for convalescents from respiratory affections. The sufferer from pulmonary tuberculosis, even in its early stages, would do well, however, to enter a sanatorium. Moderate winds, although invigorating for the convalescent, were never advisable for the consumptive, and the two sanatoria situated in that area, thanks to the forethought of Dr. Burton-Fanning, who selected the sites some years ago, were placed somewhat inland. The East Coast climate was classed with that of the High Alps, but having spent some years in treating respiratory diseases in both climates, Dr. Morland said that although he had seen remarkable instances of recovery in apparently hopeless cases in Switzerland, he had seen a still larger proportion of such in England. Perhaps in the more robust type of patient progress in the Alps was more rapid than was to be expected here, but in general he thought that better results were obtained in active cases of tuberculosis if cases were treated at a low or moderate altitude. The rest which was necessary was more complete at sea-level than it could be at heights. With sanatorium patients in Switzerland drugs for sleeplessness were far more often necessary than in England.

In some further discussion Dr. PHILIP ELLMAN agreed as to the respective merits of the East and West Coasts, and said that for patients who, after making some progress, had reached a fairly stationary condition, treatment on the East Coast was more than favourable. Dr. BROWNING ALEXANDER said that a patient with a neurotic type of asthma was likely to benefit much at seaside resorts on the East Coast, but to send a patient with the

bronchitic or emphysematous type to such a bracing climate was likely to be harmful. Dr. V. H. BLAKE (Yarmouth) mentioned that there was a certain type of asthmatic who, arriving on the Norfolk coast in July or August, appeared immediately to encounter some irritating influence and had a severe attack. Patients with residual attacks of bronchitis might find it advisable to get away from the salt and hard air; a few miles inland seemed to make all the difference. Dr. W. S. C. COPEMAN referred to the need for textbook instruction on this subject; before he himself was qualified he heard scarcely a reference to climate in relation to disease, save perhaps the role of Swiss sanatoria. Dr. LEONARD FINDLAY was of opinion that, apart from the asthmatic child and the epileptic, any child might be sent to East Coast resorts. Dr. BURTON-FANNING added migraine to the short list of conditions for which some people should not be sent to the East Coast; he had seen cases in which migraine appeared to be exacerbated. Otherwise it was impossible to exaggerate the therapeutic advantages of the Norfolk seaboard.

CLIMATIC FACTORS AND DISEASE

The second discussion, over which Dr. V. H. BLAKE, president of the Norfolk and Norwich Medico-Chirurgical Society, presided, was opened by Dr. R. FORTESCUE FOX, who declared the east region to be the most bracing and invigorating part of the British coast line; it had summer warmth with a stimulating and even exciting climate. The value of it was indicated by the fact that in Norfolk and Suffolk there were some 700 homes for convalescents. Incidentally, it would be interesting to have the experience of these homes as to the reactions obtained. He gave some particulars of the international movement for the study of marine therapy which started some five or six years ago.

Dr. S. H. LONG of Norwich mentioned that for over thirty years he had been connected with a convalescent home at Cromer attached to the Norfolk and Norwich Hospital. With the exception of asthma, he could not think of any condition which was not benefited. He had been told that cases in which there was mental trouble also did not do well, but of that he had no personal experience. Years ago Norfolk was noteworthy for what was called "fen ague," now known to have been malaria, but this, following the draining of the marshes, had disappeared. Dr. W. J. PEARSON said that observations on quite young children supported the view that conditions of environment were of the very first importance; possibly it might be shown in time to come that failure to become conditioned to climatic surroundings created disease owing to metabolic disturbances. The choice of a seaside resort for the child was a simpler problem than for the adult, for it was not necessary to consider as a rule whether the surroundings were stimulating or relaxing. This part of the East Anglian coast was undoubtedly the most invigorating in Great Britain, and induced a feeling and appearance of well-being within a few hours of arrival which was almost unbelievable. With the exception of asthma, and possibly epilepsy, there was no disease from which a child should not recover quite quickly on the Norfolk coast. The effect on catarrhal conditions of the nose and throat, on tuberculous glands, and on the debilitated "lymphatic" child was very striking. Finally a meteorologist, Mr. L. C. W. BONACINA, gave some particulars of the climate of the district.

Altogether the impression left on the mind was that, as Sir STANLEY WOODWARD suggested, the association of the East Coast and the east wind is an association of words and not of facts. As for longevity, Dr. R. B. FAWKES mentioned that the average age shown on the counterfoils of his death certificate books was well over 70. To restore the balance, however, Dr. BURTON-FANNING reminded the meeting of a visitor to one of these resorts who, inquiring as to the death rate, was informed by a native, "One per person—same as everywhere else!"

On the Sunday morning a number of visitors went to Mundesley, calling at the recently opened Leicester City and County Convalescent Home, Overstrand, and returning by way of Mundesley Sanatorium, where they were received by Dr. Morland and other members of the staff.

HEALTH OF SCOTLAND *

INFECTIOUS DISEASES

Increases in the number of cases of diphtheria, enteric fever, erysipelas, scarlet fever, and acute influenzal pneumonia were recorded, the most serious being scarlet fever, which accounted for 38,887 cases as compared with 27,975 in 1932. Tuberculosis, puerperal fever, ophthalmia neonatorum, and acute primary pneumonia showed decreases. The death rate for pulmonary tuberculosis fell to 60 per 100,000 of the population, the lowest yet recorded, and that for other forms of the disease to 20, which is also the lowest recorded. During 1932 29,690 cases of venereal disease received treatment; of these 15,285 were new patients, but 28 per cent. of the latter were found not to be suffering from the disease. Of cases which were undergoing prolonged treatment, 48 per cent. did not complete the course. Among the 3,360 new cases of syphilis which came forward during the year, 13 per cent. occurred in children under 15, and 20 per cent. of all the cases were classified as congenital syphilis.

HIGHLANDS AND ISLANDS MEDICAL SERVICE

In consequence of difficulties and delays in removing patients to hospital from remote districts, the Department has taken steps to develop an air service, and negotiations were entered into with the County Council of Argyll. The responsibility for summoning the aeroplane rests with the local doctor, and the cost is defrayed partly by the council, partly from the medical service fund, and partly by the patient, if he is able to do so. The Department has also made a contribution towards the annual rental of doctors' telephones and the establishment of new telephone call offices. During the year the Post Office proposed to proceed with a trial installation for transmitting and receiving wireless messages in some of the remote islands.

NATIONAL HEALTH INSURANCE

The main provisions of the amending National Health Insurance Act (1932) came into operation on January 1st, 1933, and amended the rates of sickness benefit for women and the regulations excusing only part of the arrears from unemployed. Approximately 25,000 unemployed persons, whose ordinary insurance rights had already expired but who did not retain any medical benefit, ceased to be entitled to benefit at the end of 1933. The total sum paid out in sickness and disablement benefits in 1933 was £1,750,000, which is a reduction on the £1,807,000 for 1932, but still maintains an increase over the £1,664,000 paid in 1931. The average cost per member per week of both benefits was 4.77 pence for men and 4.12 pence for women. Cases referred to regional medical officers for examination during the year numbered 51,630 by approved societies, and 1,814 by practitioners, as compared with 60,043 and 2,251 respectively in 1932. In 23,860 cases the practitioner's certification was upheld, while in 10,403 it was reversed. Among the cases not examined, final certificates had been granted in 10,839 instances, and a test over six months showed that fully 90 per cent. of final certificates were issued either immediately prior to, or within two days of, the doctor being informed that the insured person was to be examined by the regional medical officer. The provision of medical benefit by insurance practitioners continued on the usual lines, and some 1,900,000 insured persons were entitled to receive medical benefit from 2,030 practitioners under contract with insurance committees. The number of cases of alleged failure by practitioners to comply with their terms of service was only twenty-nine during the year, and in ten of these the Department decided that deductions should be made from the practitioner's remuneration of sums varying from £1 ls. to £25. There were nineteen claims by practitioners for fees from insured persons in respect of services which did not fall within their contract, and in eighteen of these cases both the local medical

* The first part of this notice of the Annual Report of the Department of Health for Scotland appeared on June 30th (p. 1179).

committee and the insurance committee supported the claim. The number of certificates of incapacity issued during the year was 400,052, representing approximately one commencing incapacity for every five insured persons. The average duration of all incapacities which terminated during the year was 45.7 days as compared with 46.4 days in 1932. Reference is made to the clinical research into valvular heart disease, including treatment, which began on July 1st, 1933, and which will continue for a year or such other period as may be decided. The number of chemists' shops at which insured persons could obtain drugs and prescribed appliances was 1,792, and during the year 448 samples of drugs and 142 appliances were tested. In only fifteen of these cases were the circumstances considered to be such as to warrant withholding a portion of the remuneration.

The report contains over fifty pages of statistical appendices. It may be obtained from H.M. Stationery Office, 120, George Street, Edinburgh (price 3s. net).

England and Wales

Memorials to Manson and Ross

With the incorporation of the Ross Institute in the London School of Hygiene and Tropical Medicine another chapter has opened in the history of the control of tropical diseases. The official ceremony took place at a reception at the school on June 29th, when the Earl of Athlone, as Chancellor of the University of London, unveiled a memorial tablet to Sir Patrick Manson and a bust of Sir Ronald Ross. The proceedings opened with the reception of the guests, on behalf of Sir Austen Chamberlain, by Sir Charles McLeod and Sir Herbert Read. At the unveiling ceremony which followed, Lord Athlone said that the occasion was one for honouring the memory of Manson and Ross. Manson had the vision and courage to inspire teaching and research in tropical medicine and to lay the foundations of a nobly conceived centre of research. He was a pioneer in the untrodden paths of medicine. After leaving Scotland at the age of 21, he went to Formosa and worked there and in China for nearly a quarter of a century in isolation. He discovered that the mosquito acted as a host in the transmission of filaria. He also discovered several new parasites of man and several new diseases. In 1897 he set himself to found the London School of Tropical Medicine and laid the scheme before the then Secretary of State for the Colonies, Mr. Joseph Chamberlain, with the result that in 1899 the original school was built and organized in connexion with the Seamen's Hospital Society in the Albert Docks. Sir Ronald Ross, the Chancellor continued, was, in turn, inspired by "the father of tropical medicine" as Manson was called, to study malaria, especially its prevention. While serving in India he realized that many tropical diseases were preventable, and that malaria was a greater scourge than either plague or cholera. His study of the mosquito and the spread of malaria led to the investigation of insects as disease carriers, and the discovery that the germs of yellow fever, relapsing fever, sleeping sickness, etc., all had insect hosts. The tablet and bust were received on behalf of the school by Sir Charles McLeod, the former being presented by Lady Manson and family and the latter by the sculptor, Lady Welby. The guests at the reception found a wealth of interesting exhibits and demonstrations, which had been arranged especially to illustrate the work of the school in relation to industry. They included living insects noxious to man and protozoal parasites causing disease in man, and exhibits concerning bacterial fermentation, the adulteration of food and its detection, safe milk and pasteurization, health propaganda, etc. In addition there were exhibits illustrating

the discoveries of Manson and Ross, a lecture-demonstration by Dr. G. P. Crowden on "Insulation against Heat and Cold for Human Comfort," and a film presentation entitled *The Rat Menace*.

Wakefield Municipal Hospital

The Minister of Health on June 29th opened the new Wakefield Municipal Hospital for notifiable diseases; this will now take the place of the very out-of-date isolation hospital, erected in 1874, which contained only thirty beds. The new series of buildings accommodates ninety-seven patients, and comprises two fever ward blocks, each with twenty-four beds, one diphtheria pavilion containing seventeen beds, one cubicle block of twelve beds, one discharge block with four beds, and a tuberculosis pavilion with sixteen beds. The administration block contains forty-two beds for the staff; there are separate residences for the medical officer, the engineer, the ambulance driver, and the gate porter. The grounds are adequate for the outdoor recreation of patients and for future extension of the hospital if required. The ward blocks and day rooms are situated to secure the maximum amount of sunlight. Verandas with glass roofs extend the full length of the south side of each block, and will accommodate beds in suitable weather conditions. There is a day or recreation room in each ward block for the use of convalescent patients. Single-bedded wards are also provided. The ground area round the tuberculosis pavilion will be separated from the part of the ground reserved for fever patients. The cubicle block has twelve single-bedded wards with glazed partitions between them, enabling the nurse in the central day room to have direct observation of all patients in this block. It is hoped to add an x-ray department at some future date. The diphtheria pavilion has an operating room behind it, but the sterilizers are contained in the adjoining duty room. Steam-heated radiators have been installed, and the electric lighting includes a shadowless type of operating-room electric light. In the tuberculosis pavilion there are two six-bedded wards, and four single-bed wards, two day rooms, and a duty room. A veranda with a glazed roof extends the full length of the block on the south, and the wards on this side can be opened out by means of glazed sliding screens. The pavilion is placed away from the other blocks, and on a more sheltered and level part of the site.

Royal London Ophthalmic Hospital

The first part of the programme of extension, reconstruction, and modernization of the Royal London Ophthalmic Hospital (Moorfields) was completed in December, 1930, by the provision of the private ward block, together with the necessary increased accommodation for the nursing staff. The second and larger part of the scheme was begun in March, 1933, with the demolition of the out-patient department, embodying the minor operation theatre, dispensary, spectacle room, almoners' offices, orthoptic department, pathological and bacteriological laboratories, museum, and library. To provide accommodation for these without serious reduction of the bed accommodation temporary structures were erected. Day rooms were converted for use as an out-patient department and wards, but the bed complement of the hospital has had to be reduced for the time from 152 to 136. At the end of last year the whole of the glazed stonework of the front elevation had been completed, and in the annual report for 1933 of this institution the committee of management expresses the hope that it will be possible to occupy the new buildings in the late autumn of this present year. Despite the fact that the main financial activities have been concerned with the raising of money for the new buildings, a surplus of £989 of income over expenditure was achieved on the year's working.

Scotland

Honorary Degrees at Edinburgh and St. Andrews

At a graduation ceremonial held in the University of Edinburgh on June 28th, with Principal Sir Thomas Holland presiding, a large number of graduands received degrees in Arts, Commerce, Divinity, Law, and Science. Among seventeen recipients of honorary degrees were two members of the medical profession who received the Doctorate of Laws. The Dean of the Faculty of Law, in presenting Dr. Robert Hutchison, physician to the London Hospital, said that the latter was now an undisputed leader in the medical profession of London. He was well known for rapid and accurate diagnosis, for resourcefulness in treatment, and for expert knowledge of dietetics and the diseases of children. What he had learned in practice he had put at the disposal of his medical brethren in lectures and writings of exceptional authority and wide popularity. Much might be said of the confidence and respect he enjoyed among his professional colleagues, and so high did his reputation stand as a clear thinker and an admirable debater, equipped with a power of quick repartee and a keen sense of humour, that, had he elected to follow the law, he would assuredly have been a formidable competitor for its most glittering prizes. In presenting Dr. Theobald Smith, Director Emeritus of the Department of Animal Pathology of the Rockefeller Institute for Medical Research, the Dean said that the University was honouring a pioneer in bacteriology and comparative pathology. Dr. Smith was a veteran scientist who could look back on a lifetime of achievement in medical and veterinary research, during which he had held several important scientific and academic posts in the United States. He had probably been the first to call attention to the experimental production of a deficiency disease and to reveal the existence of serum anaphylaxis. He had also led the way in differentiating between the human and bovine types of tubercle bacilli. It was especially appropriate that in the year in which the Royal (Dick) Veterinary College had become affiliated to the University of Edinburgh they should be honouring one who had contributed so largely to the advancement of the science which that college represented in Scotland.

At a graduation ceremony at St. Andrews University on June 29th, over which Principal Sir James Irvine presided, about 160 students received degrees in Arts, Divinity, Law, Medicine, and Science. Among the seven recipients of honorary LL.D. degrees were two members of the medical profession: Sir Frederick Gowland Hopkins, Professor of Biochemistry in the University of Cambridge and President of the Royal Society, who in 1929 was awarded the Nobel Prize in Medicine for his work on vitamins; and Lord Moynihan, Chairman of the Medical Advisory Board of the Army, late President of the Royal College of Surgeons of England, and founder of the Association of Surgeons.

Edinburgh Royal Blind Asylum

At the annual meeting of the Edinburgh Royal Blind Asylum and School the Rev. Dr. Thomas Burns, chairman of the institution, said that there were 124 children at present in the school, a greater number than ever before. Attached to the school was the only Braille publishing house outside London. This employed twenty blind persons, and produced not only many books and magazines but a number of musical publications which would not otherwise be available to the blind. Recently an American musician, having failed to find any institution

in the New World which could transcribe the orchestral score of *Brigg Fair*, had had this work done with complete success at the Edinburgh Blind School. Subscriptions for the year had shown a slight increase. In recent years, however, the directors had had financial anxiety through the difficulty of finding sufficient work for the blind, and the number of industrial workers on the roll was greatly in excess of requirements. The deficit for the year's working, which amounted to £8,400, could only be reduced in the future by greatly increased sales of the work of blind persons. Various steps had been taken to effect economy, and it was hoped that the deficit would be considerably reduced next year.

Edinburgh Dental School

A meeting for the distribution of prizes at the close of the session was held in the Incorporated Edinburgh Dental Hospital and School on June 29th, when the dean of the school, Mr. A. C. W. Hutchinson, presided, and Mr. J. W. Dowden presented the prizes. The Dean said that the work of the hospital had been satisfactory. The number of students on the register at that time was 158, so that the Edinburgh Dental School was the second largest in the United Kingdom. During the year thirty-nine students had obtained the L.D.S. diploma. In nearly all departments the competitive results had shown a remarkably high standard, and in general subjects taken in competition with medical students the dental students had earned their full quota of medals and certificates.

Reports of Societies

STUDY OF DISEASE AS AN INTELLECTUAL STIMULUS

DR. W. A. PUSEY'S ORATION

The annual Prosser White Oration before the St. John's Hospital Dermatological Society was given on June 27th by Dr. WILLIAM ALLEN PUSEY of Chicago, formerly President of the American Medical Association and of the American Dermatological Association, and present editor of *Archives of Dermatology and Syphilology*. The oration bore the curious title of "Disease, Gadfly of the Mind," which, being interpreted, meant the stimulus which the study of disease, especially skin disease, in all ages has given to the development of the intelligence.

Dr. Pusey began by remarking that there were few incentives to thought that had more constantly prodded man in his intellectual progress than the injuries and pains and illnesses that had beset him. In Egypt, Babylonia, Greece, from Imhotep to Hippocrates, medicine had been one of the chief concerns of the mind. Reactions to the study of disease accounted for the greatest heights of early independent thought. Aristotle found biological facts so thought-provoking that they occupied no small part of his attention. In the Middle Ages, when men were reduced almost entirely to superstition, the imperious necessity of getting relief from misery made them give at least some consideration to their bodily ailments, and when the revival of learning did come the interest excited by the biological sciences was not surpassed by that of any others. In our own time, Pasteur the chemist, for example, found the field for the development of his unexampled genius in the problems of disease. It was a frequent assumption that medicine and the biological sciences had lagged behind the other physical sciences. The Orator maintained the opposite position, that medicine from the beginning of history could claim to be the mother of the sciences, and always one of the most active and reproductive members of the family.

ROLE OF DERMATOLOGY

From the beginning of medicine dermatology had constituted one of its major interests. It loomed large in the earliest literature of Egypt and Babylonia, and right through Greek, Roman, and Arabian medicine. In the Middle Ages probably the best illustration of the vitality of medicine was furnished by dermatology. The plague of leprosy, beginning about 500 A.D., and reaching its height in the Crusades, had two useful effects on the growth of medicine, being specially responsible for the development of hospitals, and giving a new impetus, as did syphilis in a later age, to the objective study of diseases. He proceeded to cite evidence that the study of leprosy brought dermatology and medicine in general to a higher plane of knowledge in this period. As for syphilis, it was unnecessary to enter into the details of its history in the last four hundred years in order to emphasize the importance of syphilis as a gadfly of thought. It had engaged the ablest minds of medicine, from Paracelsus and Fracastor to Virchow. Turning to other skin diseases, he instanced in particular the work of Ramazzini, about 1700, in occupational dermatoses, and another striking illustration in this field of dermatology was the description of the chimney-sweeps' cancer of the scrotum by Percivall Pott in 1775—a pioneer landmark in the history of our knowledge of the causes of cancer. Subsequent research had continued to emphasize the influence of long-continued irritation in cancer production. Pott's penetrating genius hit upon the substance, tar, which recent research had shown to be the one of all others most definite in its capacity to produce cancer by irritation.

The Orator mentioned a recent leading article in the *British Medical Journal* emphasizing the importance of the skin in the study of cancer, in which the reflection was made that in the skin as nowhere else was given the opportunity for the recognition and study of cancer in its early stages, for the tracing of the direct relationship of carcinogenic influences and of the relation of cancer to occupations, for the study of the general structure of tumours in their early stages, and for the accumulation of statistical records of many of the exact details of cancer which were elsewhere difficult or impossible of observation. Another landmark of peculiar significance in the modern progress of medical thought was the beautiful demonstration by Bonomo at the end of the seventeenth century of the causal role of the itch mite in scabies. The Orator made some long quotations from Bonomo's writings, and concluded that there was no more scientific or conclusive argument against the humoral and other hypothetical pathologies of disease than Bonomo's simple demonstration of the production of inflammation in the skin by the invasion of animal parasites.

The skin was still a happy hunting ground for investigators of the facts, particularly the minute facts, of biology and medicine. In it biological and pathological phenomena were spread out for direct observation. Unna, in 1896, wrote that a "thorough study of cutaneous pathology must have a great bearing on general pathology. Inflammation and the formation of tumours have a very close relation to the skin, for there they can be observed with the naked eye. A whole series of processes are visible only on the skin." The reality of these advantages had been abundantly established in modern study, which had resulted in a continuous series of new facts significant for medical science and art. A good modern illustration was seen in Thomas Lewis's use of the cutaneous circulation to illustrate methods of physiological investigation and interpretation of the phenomena of the peripheral circulation under natural conditions. Another recent illustration of the usefulness of the skin in the study of large biological subjects was Cockayne's study of inherited abnormalities of the skin and its appendages, with a view to the light which these abnormalities threw upon genetics. The successful study of the finer details of tissues dated from the perfection of section cutting and the introduction of differential stains by Carl Weigert.

¹ 1933, ii, 67.

who first applied these methods to the skin—to a study of the eruption of small-pox.

GENERAL IDEAS OF CONTAGION

The general ideas of contagion and the demonstration of its minute causes were likewise in great part the result of the study of diseases of the skin. The recognition of contagion went back to very early times in the history of medicine. In the Middle Ages the bubonic plague, leprosy, and, later, syphilis, were the diseases which crystallized the idea in concrete form. Hauptman of Dresden, and Lange of Leipzig, independently, in the seventeenth century, even before the demonstrations of micro-organisms by Leeuwenhoek, suggested that all skin diseases were of parasitic origin. The first definite knowledge of living contagions was reached after the modern microscope made the beginnings of bacteriology possible. The first fact in microparasitology was Bassi's discovery in 1837 that muscardine, a disease of silkworms, was due to a micro-organism, and the first fact in human microparasitology was Schönlein's discovery in 1839 of the organism of favus; while in 1842 Remak, Schönlein's pupil, cultivated the organism of favus on apple, and from the culture reproduced the disease on his own arm—the first artificial production of a disease by inoculation with a specific micro-organism.

The skin stood out with equal significance in the history of bacteriology in the strict sense of the word. Modern conceptions of infection and immunity had been influenced profoundly by studies of the skin manifestations of the exanthemata, conceptions which originated with Thomas Fuller, and were first expressed in his remarkable *Exanthematologia* in 1730. Fuller was a country doctor, and spent his professional life in practice at Sevenoaks. The skin was likewise the site of the first studies of the manifestations of what was now called allergy and sensitization. These were made and interpreted by a remarkable group of Englishmen and Scotsmen as early as the last years of the eighteenth century and the first of the nineteenth in connexion with vaccinia. The earliest description of the allergic relationship between small-pox and vaccinia was given by Jenner, and the early studies by Cox, Bell, Adams, Willan, Moore, and Monroe were remarkably accurate studies in allergy, all of them upon the skin. The conceptions of immunity had their origin in dermatological observation, and still to-day the fruitful study of immunity was largely a study of the manifestations of the details of its processes as they occurred in the skin. In a paper recently presented before the American Association for the Advancement of Science (for which he was awarded the annual prize of that organization for the most significant work brought before it) Reuben Kahn had shown that the skin possessed a degree of immunity more than ten times as great as that of muscle or brain tissue or blood plasma.

THE SKIN AND THE GENERAL HEALTH

From time immemorial the influence of the general health upon the skin had been emphasized, perhaps over-emphasized. The opposite conception, the influence of the skin upon the general health, was a new one, or at least a new realization of its importance was arising. Only lately had it come to be understood that the skin had functions of the highest usefulness in the maintenance of health, that, especially under the influence of light, it performed chemical functions of vital importance, and that it was probably the chief organ in the mechanism of immunity. The knowledge that the skin was influenced by certain disturbances of the ductless glands went back at least a century, to the time when Addison described the disease known by his name. It was not without significance that this determination of Addison's disease was made by a pupil of Willan, who was familiar with skin diseases and described scleroderma.

A new fact was now emerging, that the skin itself was also an organ of metabolic activity, which was important in maintaining a balance of viscous health. How extensive the ramifications of that discovery might prove could

not be prophesied, but it had important possibilities of useful knowledge.

Finally, the Orator glanced at the definite information of the importance to the general health of the metabolic activities of the skin which had been gained in connexion with the vitamins. It had now been shown by Lucas of the Lister Institute that the production of vitamin D might not simply be through the effect of ultra-violet rays on the ergosterol in the fat which was accumulated in the epidermis, but that the corium possibly participated in this production.

Returning to his main theme, that diseases had been among the greatest incentives in the making of the mind, and that among diseases few had been as great in this respect as diseases of the skin, Dr. Pusey said that his excursion might be regarded as a fanciful, perhaps a trivial, speculation; but he thought not. There was nothing more important in the evolution of civilization than those goads of the mind, relatively few, which first gradually lifted part of the human race out of barbarism. The way the mind had grown through its reactions to its experiences was one of the basic and most inspiring facts of human history. His address, so far as it was a consideration of skin diseases as a stimulus of the mind, was not a glorification of dermatology, but of its field. No specialty had a proprietary interest in its own field, or could, if it would, exclude other workers from it. But in increasing proportion the contributions to biological knowledge in modern times had come from men whose interest was the skin and its diseases. His point, however, was the role that skin diseases had played in the advancement of medical knowledge, and, more impressive still, in the making of the mind—a role which was a challenge to dermatology to be worthy of its heritage and its opportunity.

LIPIODOL AND X RAYS IN PELVIC TROUBLE

At a meeting of the North of England Obstetrical and Gynaecological Society, held in Newcastle-on-Tyne on June 8th, Dr. FARQUHAR MURRAY read a communication on the value of lipiodol and x rays in the diagnosis and treatment of pelvic mischief.

The technique consisted in injecting 8 c.cm. of slightly warmed lipiodol with Bengué's screw syringe, the patient being under anaesthesia and the vagina and cervix having been swabbed with acriflavine. Dilatation was not done, and the cervix was clamped to the cannula by a vulsellum. The patient was sent direct to the x-ray department with the vulsellum still clamping the cervix, and a second photograph was taken in twenty-four hours. The need for the second photograph was imperative for correct interpretation, because the primary photograph might be misleading. In a normal case the shadow of the uterine cavity, attenuated threads representing the tubes, and a mass (usually well defined) near the ostia, were visible. In twenty-four hours the uterine and tubal shadows had disappeared, and there was merely diffuse blurring. The presence of vaginal shadow and clinical observation indicated that drainage in these cases was both per abdomen and per vaginam. Normal tubes were distensible; they were also contractile, and this was a disadvantage with the thinner neo-hydriol, as far as the shadows were concerned. Interpretation of tubal and terminal shadows was most important. Obviously if no solution passed into the tubes cornual occlusion was present: from a diagnostic point of view the state of the tubes was unknown, and therapeutically the injection was futile. Again, a proved terminal occlusion with a large dilated tube was a different proposition from a proved terminal shadow with the thin line representing the tubes. The first suggested that apart from the occlusion the tube was normal, while the latter suggested an interstitial fibrosis, or at least some abnormality. Again, tubal distensions at the primary examination were hard to interpret, but a residual shadow indicated clearly imperfect tubal drainage. Terminal shadows were difficult to explain until the second photograph showed whether

they were open or closed, and, in brief, whether the solution was free in the peritoneum or encysted in a sealed abdominal ostium.

Sterility.—Lipiodol provided a method of obtaining information in cases of sterility which prevented purely speculative and often futile operations. There were three main types of case. In the first the uterus was shown up in the photograph, but not the tubes. Advice was given against operation in this type, as the state of the tubes was unknown and a plastic operation at the cornua produced results too speculative to be justified. In the second type, the solution distended the tubes to the abdominal ostium, which was sealed. Terminal blobs of solution were noted in twenty-four hours. This showed a patency and normality of the tube as far as the ostium, and salpingostomy was indicated. In the third type the solution passed to the abdominal ostium merely as a fine thread: in twenty-four hours there were only two small dots corresponding to the ends of the tubes. This, in Dr. Murray's opinion, probably meant fibrosis of the tube; the result of salpingostomy in such a case was very doubtful. Sometimes lipiodol with an x-ray photograph revealed an error in the insufflation test.

Inflammation.—In cases of pelvic pain where examination was negative and diagnosis rested between urinary and tubal infection, Dr. Murray, with the idea of avoiding operation if possible, proceeded as follows. The general condition and urinary tract were treated for two months, citrates, bromides, and aperients figuring prominently in the regime. If this did not cure, injection of lipiodol and x-ray examination was done. Laparotomy was advised if the solution did not enter the tubes. If it entered, the tubes but did not escape into the abdomen, or if it passed into the abdomen freely with normal photographs, further symptomatic treatment was recommended. It might be asked how one knew that the tubes were at fault if the shadows appeared normal. One could be reasonably certain if the patient admitted that the injection made the pain worse, and by the indirect evidence that in some cases the pain had been ultimately relieved. It might also be asked why operation was not done if a definite lesion was proved to exist. The answer was that the damage could not be gross, or it would have been palpable: if the solution reached the ends of the tubes, though it failed to reach the abdomen, this proved that there was tubal drainage, and justified optimism. Also some of these cases with a definite pathology were relieved by the injection. If in such cases the pain remained after a further two months' treatment, operation was justified. The main trouble was an associated chronic perimetritis, if appearances at operation were to be believed. Sometimes cases of chronic cervicitis and vaginitis required radical disinfection. For some time past it had been the rule to inject lipiodol and have these cases radiographed, whether there was complaint of pelvic discomfort or not. Definite proof of tubal disease was sometimes found even without any complaint of pain.

Pre-operative Diagnosis of Inflamed Appendages in Young Women.—In this class of case the woman might be in her twenties and childless. She had pelvic pain, and a diseased appendage was found. The object of operation was often to relieve an unpleasant symptom and restore health. The importance of maintaining or restoring fertility might be overlooked. Lipiodol and x-ray examination would give information not only about the diseased appendage but also about the one which it was hoped to conserve. This might mean intelligent instead of speculative treatment at laparotomy. Dr. Murray added that in spite of x-ray diagnosis he did not attempt salpingostomy without having the insufflating cannula *in situ* at the time of operation and confirming patency to the salpingostomy opening.

Lower Segment Caesarean Section

Mr. HARVEY EVERS read a communication on experience of 150 cases of the lower segment Caesarean section operation. The results are shown in the accompanying table.

Whole Series (150)		Suspect or Septic Cases (123)	
Mothers died ...	4 (2.6 per cent.)	Mothers died ...	4 (3.2 per cent.)
Babies: stillborn, 5	11 (7 per cent.)	Babies: stillborn, 4	10 (8.1 per cent.)
died ... 6		died ... 6	
Morbidity ...	29 (19.6 per cent.)	Morbidity ...	27 (21.1 per cent.)
Cases Operated on Before Labour (27)		Failed Forceps Cases (24)	
Mothers died ...	0	Mothers died ...	3 (12.5 per cent.)
Babies: stillborn ...	1 (3.8 per cent.)	Babies: stillborn, 2	5 (20.8 per cent.)
died ... 0		died ... 3	
Morbidity ...	2 (7.4 per cent.)	Morbidity ...	14 (58.3 per cent.)
Suspect Cases, excluding Failed Forceps (99)			
Mothers died ...	1 (just over 1 per cent.)		
Morbidity ...	13 (just over 13 per cent.)		

He considered these results very satisfactory as a whole; they compared favourably with previously published series. The figures for suspect cases were extremely good, considering that many of these would have been regarded by some obstetricians as unfit for Caesarean section. The failed forceps group, as might be expected, gave the worst results, but in view of the serious condition of several of the patients before operation he thought them reasonably good; 75 per cent. of the maternal, and nearly 50 per cent. of the foetal, mortality occurred in this group, and the morbidity was strikingly high. It would be difficult to produce a parallel series of cases treated by the classical method with such satisfactory results.

Indications.—The great majority were cases of contracted pelvis. In some the operation was done after trial labour, and the basic factor at fault was poor uterine action rather than disproportion. It was in these cases that the lower segment approach had special advantages over the classical method: obviously it reduced the number of inductions of labour. In five cases there was a placenta praevia, but in only three of them was it the real indication for operation; there was troublesome haemorrhage, and Mr. Evers was not impressed with this means of access for this type of case. Fibroids were present in four cases, but provided the indication for intervention in only one. There were several cases of breech presentation, several elderly primiparae, and one of sacro-coccygeal tumour. In three cases operation followed induction of labour which had failed; one of them showed severe morbidity. In one case the cord was a hundred inches long and was round the neck nine times.

Technique.—Mr. Evers agreed with Stabler that a douche, followed by antiseptic treatment of the vagina and cervix, was sound practice, though he had only had this carried out on rare occasions. Anaesthesia had usually been general, never local; spinal anaesthesia was used twice.

The patient was kept horizontal: a slight Trendelenburg position encouraged flow of septic matter from the vagina into the uterus. The ordinary low vertical subumbilical transperitoneal incision was adopted: on two occasions when the extraperitoneal route was used this proved unsatisfactory. The bladder must be quite empty. The peritoneal cavity was packed off by gauze. The peritoneum of the utero-vesical pouch was incised transversely, and the bladder pushed down. This was only liable to be difficult in repeat cases. In sixteen of the early cases a transverse uterine incision was used: it had, however, no advantage in delivering the head, bleeding was more severe, and it was difficult to prevent tearing into the blood vessels at the sides. A vertical incision was now used, the uterus should be pushed into the middle line first, and any torsion present undone. An accurately median vertical incision minimized haemorrhage; it should begin as low as possible, and should be extended upwards by scissors. Extension downwards of the incision during delivery might wound the bladder, and extension or tearing up into the upper segment increased bleeding and weakened the scar. The membranes were preserved while the incision was made: then 1 c.cm. of pituitary extract was injected into the uterine muscle. Bleeding from the cut edges was controlled by catch forceps or by special forceps designed by Mr. Evers. The head was delivered by lifting the caput and moulded part up into the wound; then pressure was exerted on the fundus, the head being kept fully flexed. The previous injection of pituitary was a great help. In difficulty, one or both blades of a pair of short forceps were used. This was often necessary in cases not in labour or when the head was floating. On 1 blade was used in twenty cases, two blades in ten cases, and the feet were extracted first in eight cases of deliberate version or of breech presentation.

In fifteen of his early cases he delivered the placenta *per vias naturales* at the end of the operation. Case 73, in which the retained placenta had to be manually removed, induced him to discard the method. This was a failed forceps case, and the manual removal might have contributed to the fatal result. Since then he had always waited for the placenta to separate, and in many cases it was expelled into the lower segment and could be removed by roping the membranes. In a few the hand must be passed into the upper segment to remove it, but this should be avoided if possible. The uterus was closed by two layers of sutures. The first was always continuous: it avoided the decidua and inverted the cut edges. The second was continuous if bleeding was difficult to control or if the lower segment was thin, but interrupted if it was thick: this layer took in the main part of the uterine wall and overlying fascia. The peritoneum was sutured by continuous catgut. There was complete lack of tension, apposition was excellent, and healing sound. In suspect and failed forceps cases, a piece of tissue drain was split at one end: one portion drained the uterine wound, and the other the utero-vesical pouch. It should not be removed too soon.

Advantages.—Mr. Evers summed up the points in favour of the method as follows: (1) Trial labour could be made with much less risk. This diminished the number of Caesarean sections and inductions. (2) The danger of sepsis was much less, and if it occurred it was likely to be pelvic and not general. (3) There was a definitely lower maternal mortality in suspect and failed forceps cases. (4) The operation, though technically more difficult, was accompanied by much less haemorrhage. (5) The convalescence of the patient was much less stormy. (6) The risk of subsequent rupture of the scar appeared very slight. The only disadvantage of the operation was that it was admittedly sometimes difficult to do in cases not in labour.

CORRESPONDENCE

Pyloric Stenosis

SIR,—I have read with great interest the article by Dr. H. L. Wallace and Mr. L. B. Vevill, and I should like to congratulate them on their careful and painstaking *résumé*. A chart is given showing the birth weight and the weight on admission to hospital, in which there is a difference of 2 lb. There is undoubtedly a loss of weight before the condition is recognized and sent for treatment, but it is doubtful if the difference is quite so great as the authors find—at any rate in this part of the country. It is never safe to rely on birth weights, as so often the midwife makes it more than it really is; and again, so many infants are weighed at birth on a spring balance which is often quite inaccurate. In my experience 8½ lb. for a pyloric baby is generally too high, especially as so many are first babies.

Cases of pyloric stenosis seem to be recognized earlier in this part of the country than in Edinburgh, and the large proportion of my cases have come soon after the baby is 4 weeks old, instead of 6½ weeks, as in the authors' cases. This is of the greatest value, and the mortality in my series of ninety-nine cases is 15 per cent. This mortality can only be further reduced by not merely getting them still earlier, but also by strict attention to every detail. Every infant is operated upon as soon as the diagnosis is made. Immediately before operation a glucose saline is given and the stomach washed out, the latter to help the surgeon so that there is no vomiting or distension of the organ at the time of operation. As regards the anaesthetic I have a great preference for gas and oxygen given by a skilled anaesthetist. This enables the surgeon to do the operation as quickly as possible, and there is a minimum of shock. A detail worth attention is to run saline into the abdominal cavity through a catheter as the surgeon is stitching up. Highly skilled individual nursing after operation is essential, and this is borne out by the fact that the mortality in private cases is almost negligible. If the infant is in a ward he must

be most carefully guarded against intercurrent infections like enteritis.

I agree with the authors that the outstanding features in all cases are the projectile vomiting, visible peristalsis, and constipation, and that the presence of a tumour which can be felt is of little significance. Breast-feeding is always of great value, and arrangements should be made for the mother to continue this, although the baby is in hospital.—I am, etc.,

HUGH T. ASHBY, M.D., F.R.C.P.

Manchester, July 1st.

SIR,—In the excellent article by Dr. H. L. Wallace and Mr. L. B. Wevill, analysing 145 cases of pyloric stenosis (*Journal*, June 30th, p. 1153), there are three striking features: (1) the high mortality; (2) the small percentage of cases in which the tumour was felt; and (3) the lack of information about the feeding methods employed.

With regard to the first point, pyloric stenosis is essentially a condition to be treated by "team work." The pre-operative and post-operative technique are the paediatrician's special care, and on him should rest the onus of deciding when to get the surgeon to perform the operation of mechanical relief, so that the infant's "poor general condition" should never enter the statistics as an operative mortality factor. Pre-operative transfusion, intravenous and subcutaneous dextrose, or Hartmann's solution can in almost every case give the surgeon a fair task. The post-operative technique is just as important, and includes further transfusion or intravenous and subcutaneous fluids and a routine feeding schedule. While working in America some six years ago I had the opportunity of seeing Hartmann and Clopton's pyloric stenosis team work, and their results were most impressive (fifty-two cases with a 4 per cent. mortality). Later, in Stockholm, I found that Ernberg, at the Sachska Barnsjukhuset, had a similar mortality figure treating all his cases medically—with the advantage of a resident wet-nurse staff.

As to the palpability of the tumour, the oftener the infants are examined the higher the percentage of cases in which the pylorus is felt. In some infants it can only be felt when the stomach is empty, in others only when the stomach is full, but 60 to 70 per cent. is a more usual figure than the 24 per cent. quoted.

Finally, the problem of how to feed these infants after operation; whether they be weaned or still on the breast the adoption of a routine technique will go far towards diminishing enteritis. Such a schedule as advocated by Clopton and Hartmann (*Surg., Gynecol. and Obstet.*, 1928, xlvii, 527) gives excellent results.—I am, etc.,

Liverpool, July 2nd.

WILFRID F. GAISFORD.

Ligature of the Innominate Artery

SIR,—Mr. Souttar's interesting description of a carefully planned and successful procedure for the cure of innominate aneurysm (June 16th, p. 1066) will be read with interest, especially by those surgeons who have had the opportunity of ligaturing the innominate artery. Such opportunities are few and far between. In the future they will be still less frequent, for medicine has obtained the mastery over syphilis, and early attention is given by physicians to other predisposing causes. Traumatic subclavian aneurysm is a rarity. From time to time instances of ligature of the innominate artery have been carefully tabulated. Up to and including the year 1922 approximately fifty-seven cases, with nineteen recoveries, had been recorded. Mr. Granville Chapman, in the current

number of the *Journal*, adds another case to the list given by Mr. Souttar. He recalls his successful ligation of the innominate artery in 1928 (*British Medical Journal*, 1929; ii, 49). Two additional cases are, I think, worthy of mention.

The first patient was presented by the late Mr. Coppinger, surgeon to the Mater Hospital, Dublin, at a meeting of the Royal Academy of Medicine in Ireland on February 22nd, 1893. The record states that this was the first successful case of ligature of the innominate artery ever exhibited at any medical society in Europe.

The second case was under my own care at the Ministry of Pensions Hospital near Dublin. The innominate was ligatured in 1932 for aneurysm of the subclavian artery involving the first and second stages. The aneurysm was the result of a bullet wound received in 1915. The artery was exposed by division of the clavicle and the reflection of the inner extremity of that bone upwards, together with a portion of the manubrium sterni. Two years after operation it was reported that the patient was cured. The details of the case and the operative procedure were published in *Surgery, Gynecology and Obstetrics* (February, 1933, lvi, 257; Murphy Oration).

It is freely stated in the literature that the common carotid artery should be ligated simultaneously with the innominate in the treatment of subclavian and innominate aneurysm. But why? All admit that there is grave danger to the cerebral circulation if the double ligation is performed. Furthermore, it is difficult to understand why an additional procedure in a somewhat dangerous undertaking lowers the mortality; yet this reduction in mortality is repeatedly claimed. Is there not some fallacy in such beliefs? Could it be that operations performed in pre-aseptic days are classed together with those undertaken with modern technique? Conclusions drawn from such data are obviously fallacious. Is it not more reasonable to advocate proximal ligature of the innominate artery alone, followed by distal ligature of its branches if the primary operation fails?

On careful study of the published reports I decided, in the case of my own patient, to ligature the innominate alone. The final result justified the decision. Mr. Souttar contemplated ligature of the carotid, but abandoned his intention. He completed his operation by distal ligature of the subclavian—a far more rational procedure when conditions permit.—I am, etc.,

London, W.1, July 2nd.

W. I. DE C. WHEELER.

Cervical Cancer after Artificial Menopause by Radium

SIR,—I noted with great interest the report in your issue of June 16th (p. 1089), by Mr. Maslen Jones, of a case of carcinoma of the cervix following on production of artificial menopause by radium. I have been looking for such cases for some time, and hoped that none would ever occur, as there is such strong evidence that radium will, to a large extent, prevent cancer developing in a pre-carcinomatous condition. It will be many years yet before there are a sufficient number of patients on whom an artificial menopause has been performed to see whether statistically there is any evidence of this prophylactic effect.

When Mr. Maslen Jones goes on to say that he does not think it always possible to exclude carcinoma of the cervix by histological examination, one is left in doubt as to whether he thinks that in this particular case the growth was already present. Although he may be correct in saying that there have been and will be cases in which such efforts at diagnosis have failed, yet I cannot agree with him that on account of these possible failures in

diagnosis the hundreds of patients who can be so easily relieved of their symptoms should be subjected to a total hysterectomy.—I am, etc.,

London, W.1, June 30th.

MALCOLM DONALDSON.

Tuberculin

SIR.—In the *Journal* of June 23rd Sir Robert Philip tells us on page 1107 that, "looking through the records of the continuous use of tuberculin during more than forty years, in hospital and private practice, I remain deeply impressed by the mass of evidence pointing to its therapeutic efficacy. It will suffice to recall that I have seen tuberculous disease in almost every part of the body yield remarkably during the continued use of tuberculin." On page 1136 of the same *Journal* Dr. N. D. Bardswell is quoted as saying that "the popularity of tuberculin treatment had gradually faded away, and was not to-day seriously considered as a cure."

I agree entirely with Sir Robert Philip's statement quoted above, and have statistics of twenty-one years' work which fully bear it out. Dr. Bardswell gave tuberculin a trial for eighteen months at King Edward VII Sanatorium a little over twenty years ago. His book, entitled *Preliminary Report on the Treatment of Pulmonary Tuberculosis with Tuberculin*, 1914, shows that he had not acquired the correct method of using tuberculin, so that I am not surprised that his investigation led to no decisive result. Tuberculin, when not properly administered, may do no good, or even do harm.

I have still some reprints of a paper, "The Use of Tuberculin in Diagnosis and Treatment," and shall be glad to send a copy gratis to any of your readers who may be interested enough to send me their names and addresses.—I am, etc.,

JOHN R. GILLESPIE,
Chief T.M.O., Co. Down.

Belfast, June 27th.

Mental Deficiency and Heredity

SIR.—Of the numerous recent contributions to your columns on the aetiology of mental deficiency none has yet considered as a possible factor the psychic environment (affective contacts, interest, play, etc.) of the very young child. Dr. F. Grundy's third conclusion (*Journal*, June 30th, p. 1166) is that "feeble-mindedness and dullness are familial to a much greater extent than lower-grade deficiency," and on this point there is a general consensus of opinion. He says also (p. 1165) that the milder deficiency "has no pathology in the ordinary sense," and is analogous to stature, representing the "lower" end of a "frequency curve." If this is correct, then clearly we must exclude the notion of any specific germinal determinant—Mendelian or otherwise.

That being so, the actual mechanism of transmission of neuropathia becomes of crucial interest. We ought surely to inquire into the upbringing of high-grade defectives to determine whether the lack of interest, adaptability, intelligence, etc., is not a consequence of, or reaction to, the mentality of the mother and the general affective atmosphere of the home. Yet it seems to be taken for granted that the channel of inheritance must be organic. It is becoming increasingly evident that character, temperament, and mental stability are largely built up on the very early affective relationships to immediate relatives. Can we afford to ignore the possibility that interests and ultimately I.Q. itself owe something to the same factors?—I am, etc.,

London, W.C.1, June 30th.

IAN D. SUTTIE.

Intracranial Injury in the Newborn

SIR.—Dr. Alan Moncrieff's letter (June 16th, p. 1068) was of such particular interest to me that I hope I may be pardoned for commenting thereon.

I was quite unaware of the paper by J. N. Cruickshank, but I have observed the intense cerebral oedema in these cases, and in my own experience of post-mortems on neo-natal deaths with a history of cerebral injury this oedema is invariable. The symptoms of drowsiness, etc., appear about the end of the second or third day. They are usually accompanied or followed by twitchings and convulsions, and death rapidly supervenes. Again, as far as my personal experience goes the oedema is invariably associated with haemorrhage of some degree, more often in the nature of bruising. This bruising is to be found in close proximity to the straight sinus. The matter is of interest to the obstetrician, since to this type of injury has been ascribed the cause for stillbirth following breech delivery—a view which I feel will soon be discarded. It is more reasonable to think that the haemorrhage may at least be a factor in the later development of cerebral oedema.

On several occasions I have found what appeared to be well-marked haemorrhage in the region of the straight sinus; and, seeing that this sinus drains the interior of the brain through the vein of Galen, is it not possible that the resistance to venous drainage through the sinus, resulting from thrombosis or pressure from haemorrhage outside it, may influence the secretion of cerebro-spinal fluid from the choroid plexuses? Acting on the view that these children died from exhaustion resulting from the fits. I have always treated them with chloral, playing with time, as it were, to allow the oedema to subside. Dr. Moncrieff's treatment sounds much more rational and certainly much more successful.—I am, etc.,

Wembley, July 1st.

J. SHIRLEY CALLCUTT.

Hyperpiesia

SIR.—In his letter in the *Journal* of May 19th (p. 919), Dr. Herbert H. Brown raised several important questions that have not been answered satisfactorily in textbooks. Many readers will agree that heredity plays an important part in the production of hyperpiesia; in fact, numerous American writers regard heredity and prolonged mental strain as predominant factors. As the pace of life quickens and the struggle for existence becomes more severe for successive generations, it may be anticipated that the incidence of hyperpiesia will increase.

Regarding the final paragraph of Dr. Herbert Brown's letter, and also Dr. Graham Grant's letter (June 16th, p. 1093), I can confirm Dr. T. Izod Bennett's remarks (June 23rd, p. 1139). Records of systolic and diastolic blood pressures in a considerable number of cases of chronic alcoholism and of drug addiction show that hyperpiesia was not found unless alcoholism was accompanied by organic disease of the heart or kidneys. Even in cases of hepatic cirrhosis a systolic blood pressure of over 160 mm. Hg has not been observed, but the "pulse pressure" in cirrhosis is usually very low, being seldom more than 30 or 35 mm. Hg, suggesting that alcohol has a selective toxic action on the heart. Many persons of "apoplectic" appearance have a comparatively low systolic pressure with a high diastolic pressure. These patients do not suffer (as their friends imagine) from "high blood pressure," but from circulatory stasis, a very common symptom of chronic alcoholism, frequently associated with albuminuria and hepatic congestion, if not actual cirrhosis. This circulatory stasis is aggravated sometimes by heroin or morphine addiction.—I am, etc.,

Great Nessenden, Bucks, June 29th. C. W. J. BRASHER.

Injuries of the Knee-joint

SIR,—I have very few, if any, beliefs in the permanence of theories in either medicine or surgery, but it is refreshing to find one whose views are so firmly fixed that it is impossible to shake them. Mr. Stewart Woodman (June 23rd, p. 1142) regards rupture of the cartilage whilst the joint is extended as a heresy, forgetting that many of the heresies of yesterday are the orthodoxies of to-day. He seems so obsessed with his "old chief's" views that if a case occurred under his eyes he would probably imitate our Yankee cousin who, on seeing a giraffe, exclaimed "There ain't no such animal."

Mr. Woodman goes on to say: "There is nothing in Dr. Stewart's description . . . to prove that the injury occurred in extension." I gave the history of two cases as they were described to me, holding no beliefs one way or the other as to the position of the joint. The rail-layer was most certainly erect and rigid in all his joints, as he was supporting a very heavy weight, and a man does not do that with bent knees and bowed back. In the second case, does "he infer" the leg is never straight when running? The only addition I can suggest is a slow-motion picture. Another point I wished to make was that the foot was fixed in each case, not at all admitted by the theorists.

There is a sentence in Mr. Stewart Woodman's letter that I do not fully understand: "the presence of locking in extension—he does not say full extension." May I ask Mr. Woodman has he ever seen the knee locked in extension? If he has, assuredly the sun shines fiercely in Baghdad! I should like to ask in passing, What has the case he has quoted in the latter half of his letter to do with the mode of production, or the position of the joint, in rupture of the internal semilunar cartilage?—I am, etc.,

Leeds, June 25th.

J. STEWART.

Evipan Anaesthesia

SIR,—In reply to Dr. Montague Solomon's remarks in the current number of the *Journal* on my short article published on June 9th: His criticism is so logical and conclusive that I felt at first like a schoolboy having "an essay torn to shreds by a hard-minded schoolmaster." May I in turn venture to criticize some of Dr. Solomon's remarks.

He writes: "The patient was the same; evipan was used on both occasions; the only new factor was that of omnopon and scopolamine," and previously, "Might I suggest that the depressant effects which occurred have been due rather to the previous administration of a very large dose of omnopon combined with scopolamine, both of which are powerful respiratory depressants, rather than to evipan?" This seems hardly logical and certainly not scientific. The injection of omnopon and scopolamine was given one hour before the injection of evipan, and the alarming symptoms occurred fifty minutes after the latter. Surely if the first injection is entirely to blame the symptoms would have occurred earlier. The only conclusion one can draw is that the symptoms were due to the combined effects of all three depressants, but only after evipan had been added as a third depressant. My view of the case is as follows: In the first instance, when evipan alone was used, the respiratory centre was no doubt depressed but not sufficiently to cause any symptoms. In the second instance evipan was acting on a centre already depressed by the premedication.

Dr. Solomon's second criticism states that with a very limited number of cases—namely, two—I claim to have proved that evipan is a respiratory depressant, etc. May I point out that I have assumed the depressant action of evipan, and all I claim is that my case "illustrates"

its effects. I hope that I may still maintain that my case illustrates, but does not prove, the depressant action of evipan on a respiratory centre artificially weakened by premedication, and also its selectivity for that centre.

Dr. Solomon may be interested to know that this was the first occasion on which I have used premedication with evipan, and up to the present it is also the last case in which I have tried it.—I am, etc.,

PAUL KUHN.

Buchanan Hospital, St. Leonards-on-Sea, July 1st.

Roger Bacon and Thirteenth Century Medicine

SIR,—It is perhaps as a philosopher and Franciscan friar that Roger Bacon is best known. The versatility of his knowledge overlapped, however, the boundaries of many sciences, both pseudo and real, and he certainly deserved the title of Doctor Mirabilis. It is generally accepted that he was born about 1214 near Ilchester in Somerset: he is credited with being the inventor of gunpowder, and his work on optics led him to anticipate the camera and the telescope.

His alchemical doctrines led him in the direction of medicine. In the *Philosopher's Stone* he saw the medicine of the metals, and in his *Opus Majus* it constituted the elixir vitae, which was to cure all the ills of the flesh and to act as a specific against old age. Roger Bacon styled gold "this best of medicines because there is in it an equal or right nature and it is not subject to the corruption of any of the elements." In his treatise entitled *De retardandis senectutis* he was, however, much in advance of his time in drawing attention to the importance of diet and hygiene.

Bacon did not apply experimental evidence to medical practice in the same way as he applied his versatile and critical mind to certain other branches of learning. In this we see he was not very far in advance of the medicine of his day, except as a dietitian and hygienist, as previously mentioned. As an alternative to gold as a remedy for old age "the wonderful doctor" mentioned viper's flesh, because when the viper became old it cast off its skin and became rejuvenated. A more quaint remedy for senescence was "the bone of stag's heart," and he mentioned, as evidence of its value in promoting longevity, that a stag was captured in his own day wearing a collar dating back to the time of Julius Caesar.

Owing to Roger Bacon's influence the doctrine of signatures or signs arose later in mediaeval medicine. This theory suggested that the external form of a plant or mineral indicated its medicinal value. Lungwort (*Pulmonaria officinalis*) was prescribed for pulmonary disease because the leaves resembled the outline of the lungs. Eye-bright (*Euphrasia officinalis*), a plant with a black spot on the corolla like the pupil, was considered to be a remedy for diseases of the eye. In spite, however, of some false views, Bacon was, generally speaking, far in advance of his time, even more in advance than he dared to admit. It must be remembered he lived in an age in which the speculative mind sometimes ran contrary to the views of the Church, and therein lay a danger.—I am, etc.,

R. B. F. FRAZER, L.R.C.P. and S.Ed.,

London, N.W. 6, June 27th. Barrister-at-Law.

Traffic Control by Light Signals

SIR,—I am asking you to take up this matter in your columns because there is quite an element of medical, or at any rate physiological, science involved in the controlling of traffic by sudden signals to stop. The present system of a sudden change from the green "Go" signal to the yellow "Caution," which is technically on a par

with the red "Stop," makes no allowance at all for the fact that each person has a different reaction time, and that a fast-moving car cannot be brought to rest in the twinkling of an eye.

The point I wish to emphasize is that the designers of these signals found it necessary to provide a warning to start a car after a halt at a crossing by providing an initial red-yellow signal before the green appears, which is obviously superfluous. Amazingly, they omit to provide a green-yellow sign to fast-moving traffic, as a warning that by the time the driver has travelled 100 yards or so he must expect to find the short "Caution" yellow light appear, and be prepared to stop. In a nutshell, there is far too little warning given to relatively fast-moving main road traffic that it must stop. The present position leads to two classes of evil. Driver A, careful and correct, gets his car thoroughly in hand when he sees a signal in the distance, and takes an altogether unreasonable time about his journey in consequence. Driver B, human and in a hurry, stamps on his accelerator every time he sees a green light, in the hope of just cheating the yellow. Driving strain would be much reduced and compliance with the law made reasonable and possible if the light sequences were made as follows: Green; green-yellow (implying a definite instruction to bring the car under control and be prepared to stop); yellow (a very short safety period, during which no vehicle may cross in either direction); and red—full stop. If technical considerations demand the use of red-yellow in the restarting process, well, there is no objection.

I maintain that the present system of sudden changes imposes an unnecessary mental strain on drivers, makes the real compliance with the law very difficult, takes no account of the slow reaction time or faulty quick judgement of numerous individuals, and finally imposes a quite unfair strain on the mechanism and tyres of cars by bringing them suddenly to a stop with hard braking. I suppose my remedy is too simple ever to be considered by the ingenious people who design these signals without first consulting someone with a little common sense and a little knowledge of human psychology and physiology. For, after all, it is not wheels and engines that are being controlled by these signals; it is the human brain.—I am, etc.,

London, S.E.5, June 24th GUY BOUSFIELD, M.D.Lond.

Universities and Colleges

UNIVERSITY OF OXFORD

At a convocation held on June 20th it was resolved to confer the degree of D.Sc. *honoris causa* upon Professor Archibald Vivian Hill, O.B.E., F.R.S., M.A., Sc.D.Camb.

Boards of Faculties

The Vice-Chancellor and Proctors have made the following nominations of persons to hold office for two years as members of Boards of Faculties: *Faculty of Medicine (Ordinary Members)*: T. B. Heaton, D.M., student of Christ Church; R. S. Creed, D.M., and F. G. Hobson, D.M., Fellows of New College.

The following candidates have passed in the examinations indicated:

FORENSIC MEDICINE AND PUBLIC HEALTH—R. I. Bence, H. S. Brothribb, R. Clarke, J. P. Dewsberry, A. Farnley, R. C. Gurnan, G. F. Greenwood, T. W. Lloyd, R. McDonald, T. M. Williams.
MEDICINE, SURGERY, AND MIDWIFERY—P. C. Alexander, J. H. Bartlett, R. I. Bence, C. A. Bracher, F. M. Bazzard, A. M. G. Campbell, J. P. Dewsberry, W. F. Fawcett, R. H. Gardner, D. W. Gault, C. E. Greenwood, T. W. Lloyd, J. R. Nassim, A. G. Palm, J. F. G. Pearson, W. H. A. Picton.
PNEUMONOLOGY—W. J. C. Anstee, R. I. Bence, H. S. Brothribb, S. H. L. Bellmore, M. C. Chapman, G. A. Holston, G. O. Jell, Ned Leitch, G. L. M. McElhigott, W. P. Mallinson, D. F. G. Muir, J. C. Patten, F. M. Poulton, J. L. Reed, O. H. J. M. Telling, E. G. Tuckwell, J. W. A. Turner, G. Ward, T. M. Williams.
MATERNAL MEDICINE—W. J. C. Anstee, R. W. Barr Brown, G. H. L. Bellmore, W. W. Coppinger, D. L. Davies, J. W. B. Douglas, A. F. Foster-Carter, D. M. T. Gardner, W. E. Gibb, J. B. M.

Green, Neil Leitch, S. H. Llewellyn-Smith, K. H. A. Marshall, N. H. Martin, N. J. de V. Mather, A. T. M. Myres, N. A. Neville, R. W. Parnell, M. A. Partridge, H. M. Sinclair, M. A. Stee, N. K. Stott, D. H. Swayne, P. de B. Turtle, R. J. Stephens (St. Hilda's).

UNIVERSITY OF BIRMINGHAM

At a congregation held on June 30th the following degrees were conferred:

LL.D. (Honoris Causa).—Professor C. A. Lovatt Evans, F.R.S., F.R.C.P.

M.D.—H. P. Gilding.
M.B., Ch.B.—*†Phyllis M. Ball, *R. M. Case, *F. H. Kemp, N. Angel, T. D. Brettell, C. H. Catlin, C. H. Goodliffe, Bessie W. Goodwill, E. G. Gregory, Joan E. Hickinbotham, Christia F. Lucas, E. C. Ostler, O. C. L. Pitter, A. B. Rowlands, †C. R. St. Johnston.

* Second-class honours. † Distinction in Surgery.
‡ Distinction in Medicine.

The following scholarships, medals, and prizes have been awarded. **Richard Fenwick Post-Graduate Scholarship**: W. H. P. Cant. **Queen's Scholarships**: (third year) G. Mitchell, (fourth year) J. A. R. Johnson and A. H. Khan (divided), M. K. Tabataba, (fifth year) J. L. Collis, (final year) Phyllis M. Ball. **Ingleby Scholarships** (final year): C. H. Catlin, Joan E. Hickinbotham. **Arthur Foxwell Memorial Medals** (final year): R. M. Case, C. R. St. Johnston. **Sampson Gamgee Memorial Medal in Surgery** (final year): Phyllis M. Ball. **John Barritt Melson Memorial Gold Medal for Physiology** (third year): C. M. Fenn. **Priestley Smith Prize for Ophthalmology** (final year) and **Russell Memorial Prize**: F. H. Kemp. **Foyle Prize**: J. A. R. Johnson and A. H. Khan (divided), M. K. Tabataba. **Peter Thompson Prize in Anatomy** (third year): Frances B. Robinson.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Primary Fellowship Examination

The following have been successful at the First Professional Examination for the diploma of Fellow:

H. Ackers, H. Agar, H. R. Alban, M. Albert, H. G. E. Arthure, J. I. M. Black, I. N. Blusger, A. Bowen-Davies, W. Bullock, H. L. Cochran, L. Z. Cosin, A. G. Cross, H. L. Davies, I. H. Davies, H. K. Doctor, A. Dorman, Katharine W. Dunn-Pattison, B. H. Ellis, J. S. Ellis, F. R. Edwards, R. H. Franklin, S. G. French, H. W. C. Fuller, Dorothy M. Gladwell, H. Goldfarb, D. L. Griffiths, E. H. Hambly, A. J. Henriot, G. Hyman, W. H. G. Jessop, H. H. Langston, A. D. Le Vay, J. W. S. H. Lindahl, C. J. Longland, G. H. Macnab, R. L. Mehra, M. S. M. Mehta, D. V. R. Nadkarni, M. L. Pan, A. R. Parkes, E. R. G. Parse, E. W. Peet, G. L. Pett, J. W. Pugh, J. L. D. Roberts, A. Rose, H. L. M. Roulle, V. Sankarambal, K. C. Sarkar, P. G. Scott, H. Scudamore, W. M. H. Shaw, F. W. Shepherd, J. Sherne, J. G. C. Spencer, J. A. Stallworth, R. Strang, A. W. G. Sutherland, T. G. Swinburne, M. Talwar, R. G. Taylor, G. Townsley, H. I. Turnbull, R. E. Waterston, W. E. Wimberger, R. F. Winckworth.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—R. M. Outfin.
MEDICINE.—G. A. Bell, G. W. Bender, P. E. Cresswell, C. McK. Johnston, S. Klein, A. Lassman.
FORENSIC MEDICINE.—G. W. Bender, P. E. Cresswell, C. McK. Johnston, S. Kay.
MIDWIFERY.—W. C. Campbell, W. McC. Graves Morris, H. W. John, S. Kay, G. F. Metcalf.

The diploma of the society has been granted to S. Kay and G. F. Metcalf.

LONDON INTERCOLLEGIATE SCHOLARSHIPS BOARD

The following awards of medical entrance scholarships and exhibitions have been made on the results of the Board's examinations.

UNIVERSITY COLLEGE.—*Medical Scholarship*, L. J. Temple; *First Medical Exhibition*, W. S. Lewin; *Second Medical Exhibition*, R. Mawson.

KING'S COLLEGE.—*Warneford Scholarships*, R. G. Evans, J. L. Lawrence; *Sambrooke Scholarship*, G. T. E. Jenkins.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL.—*Science Scholarship*, R. P. Crick.

LONDON SCHOOL OF MEDICINE FOR WOMEN.—*A. M. Durd Entrance Scholarship*, J. Avarne; *Mabel Sharwan Crawford Scholarship*, M. L. Taylor.

LONDON HOSPITAL MEDICAL COLLEGE.—*Price Scholarship*, D. A. Miln.

STREATFEILD SCHOLARSHIPS

Mr. Iver Griffiths and Mr. P. Jacobs have been appointed Streatfeild Scholars, under the trust administered jointly by the Royal College of Physicians of London and the Royal College of Surgeons of England, to carry out an investigation into "The Tonsil—its Anatomy, Physiology, and the Relations of its Lymphatic Vessels."

Obituary

W. A. VALENTINE, M.D.

Major R.A.M.C. T.A. (ret.)

We regret to announce the death of Dr. William Arthur Valentine, at the age of 65, at his home in Appledore, Devon, where he settled thirty-five years ago. He was born in Co. Fermanagh, and was trained in Dublin, graduating M.D. at Trinity College in 1894. Dr. Valentine held many posts. He was district medical officer for the Northam District, medical officer of health for the Barnstaple Port Sanitary Authority, surgeon agent to the Admiralty, and medical inspector of seamen for the port of Bideford. He was also surgeon to the Bideford and District Hospital. For more than twenty years he was medical officer of the Territorial battalion of which his son, Captain A. W. Valentine, is now adjutant. He volunteered for active service in 1914, and accompanied the 1/6th Battalion the Devonshire Regiment to India. He was later in France, where he served with the 3rd Battalion Royal Fusiliers, and for the last two years of the war was attached to the Serbian Army in Salonika. For his services in Salonika he received the Serbian Order of St. Sava and that of Knight of Redeemer of Greece. He was also keenly interested in the British Legion and the lifeboat work at Appledore. He took a great interest in yachting, and had been vice-commander of the Taw, Torridge, and North Devon Sailing Club.

Dr. Valentine joined the British Medical Association immediately after graduation, and was always a very active member, attending all the Divisional meetings. On two occasions he held the post of chairman of the Barnstaple Division—1909 and 1932—and last year he attended the Dublin Annual Meeting as Representative. In 1933 he was nominated president-elect of the South-Western Branch. He looked forward with great pleasure to acting as president. As the time approached, however, he realized that his failing health would not permit him to undertake the onerous duties of president of the Branch, and it was with the greatest regret he resigned. He had already prepared his annual address on a gynaecological subject, this department of medicine being one in which he was greatly interested. By a sad coincidence his death occurred three days after the holding of the annual meeting of the South-Western Branch in Bideford, at which, had his health permitted, he would have been installed as president. His younger son, Dr. Desmond Valentine, succeeds to his father's practice in Appledore. The large attendance at the funeral service, consisting of representatives of all classes, showed the high esteem in which he was held throughout North Devon.

We regret to announce the death, on June 15th, of Dr. GEORGE JONES at his home in Church Terrace, Lewisham. He was born at Stoneleigh in Warwickshire on July 4th, 1860, and from Rugby went with a good grounding in the classics to Oriel College, Oxford, in 1879. After studying medicine at the London Hospital he graduated M.B.Oxon in 1891 and obtained the English Conjoint diplomas and the L.S.A., and a few years later the D.P.H. At the London Hospital he was in turn house-physician, aural house-surgeon, junior resident accoucheur, and senior receiving room officer; at the West End Hospital for Nervous Diseases he was house-physician; and at the Victoria Park Chest Hospital, resident medical officer. In 1903 Dr. Jones was called to the Bar, and some years later was appointed lecturer in forensic medicine and hygiene at the London Hospital Medical College, combining this with general practice in the City. He edited the third edition (1929) of the late Dr. F. J. Smith's *Forensic Medicine and Toxicology*, thus bringing up to date the published version

of the course of lectures in this subject given to students at the London Hospital. Dr. Jones had been a member of the British Medical Association for forty years, and in 1930 he represented the Lewisham Division at the Annual Representative Meeting. Occasional notes and letters by him, some of them over his signature and others over the pseudonym "*Senex*," appeared from time to time in these columns: they were generally of the nature of brief excursions down a side-path of forensic medicine or medical sociology, with perhaps one or more classical allusions, and an apt line from Juvenal or Shakespeare, or a reference to some mediaeval legal authority. This erudition was unforced: George Jones had a well-furnished mind, and could not comfortably put pen to paper without drawing upon his rich store of knowledge. We shall miss his little contributions, written in a legible scholar's hand with fastidious care for accuracy of quotation.

The death took place suddenly on June 24th, at his residence in Newton Place, Glasgow, of Dr. E. H. LAWRENCE OLIPHANT, who was well known as a specialist in obstetrics and gynaecology. Dr. Oliphant was born in 1860 at Pau, in the South of France, and after taking a medical course at Edinburgh graduated M.B., C.M. there in 1882, proceeding to the M.D. degree in 1886. After a period as resident physician with the late Sir Douglas MacLagan in the Royal Infirmary, Edinburgh, he studied for some time in Paris and Vienna and then took up practice in Glasgow. Here he was dispensary physician for diseases of women in the Western Infirmary, and physician to the Maternity Hospital; he was also associated with the Glasgow Hospital for Women in Burnbank Terrace. He enjoyed a large practice in his specialty, but retired some ten years ago. For sixteen years he was librarian to the Faculty of Physicians and Surgeons, Glasgow, a post which he resigned last year. He took a keen interest in various medical activities, having been a director of the Eye Infirmary, Glasgow, and at one time president of the Obstetrical and Gynaecological Society of Glasgow.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

THE LAW OF PARTNERSHIP

Partnership, in so far as it creates a legal relationship, is governed by the courts which administer the system known as equity. The law of partnership has been built up through centuries by the application of equitable as opposed to legal rules. ("Equitable" is here used as the adjective of "equity," and not in the popular sense.) The essence of equity is that it inquires first, not into a man's strict legal rights, but into the fairness of his dealings with others.

In the early Middle Ages the justice administered by the ordinary courts of law left much to be desired; they were often so hide-bound by precedent that they could not grant a just remedy, and sometimes they could not enforce their judgments against a powerful defendant. Aggrieved persons would petition the King on the ground that it was against the Royal conscience to permit injustice. These complaints went to the Chancellor, who as the King's confessor was the keeper of the Royal conscience, and who conducted the Court of Chancery. He gave remedies based on conscience: if a party, though on the right side of the law, acted against conscience, the Court of Chancery would forbid him to profit by his legal rights.

Nowadays all courts, in theory at least, administer equity as well as law, but the Chancery Division applies rules based on conscience to all the transactions which come under its jurisdiction, and partnership is one of these transactions. This is why a partnership is created not merely when the partners sign a typed agreement

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), and a second on June 23rd (p. 1145).

in the presence of witnesses. In the eyes of equity, the essence of partnership is that two or more persons, acting together with a view to making a profit, thereby trust one another to behave according to good conscience. Whenever, therefore, this relation of trust subsists the court may infer a partnership, with all its rights and obligations, even though nothing has been put on paper or even said between the parties. A legal partnership may be created if two or more persons share joint profits, or allow their names to appear, or behave, in such a way as to imply that they are practising as partners. Moreover, throughout its dealings with a partnership the court will apply the test of conscience to all the claims and conduct of the partners, and will not enforce an unfair agreement or allow a partner to benefit by unfair conduct, even though in strict law these might be justifiable.

WHAT IS PARTNERSHIP?

The Partnership Act, 1890, was an attempt to make a coherent code out of the mass of decisions which had been piled up in the course of time by the courts of equity. It is not a complete code and did not supersede any existing rules of law and equity, but it reduced an undigested mass of law to a series of authoritative and considered propositions. Medical partnerships, since they possess little property, and have few financial dealings, are affected only by some of its provisions. It defines partnership as the relation which subsists between persons carrying on a business in common with the view of profit. There need not be any joint capital or stock, and so a legal partnership may exist between medical men even where the goodwill itself is not a partnership asset and each partner pays his own expenses. The Act lays down several sets of circumstances which do not of themselves create partnership, such as common property, the sharing of gross returns, or even the sharing of profits, and if two or more medical men desire to work together without being legal partners there is no difficulty in framing an agreement which will allow them to do so.

In fact, it is impossible to find any definite unqualified statement, either in the Act or outside it, that if two persons do thus-and-thus they are partners, and their mutual rights and obligations shall be so-and-so. *Prima facie*, persons who share the profits and losses are partners, and the Act lays down a number of rules governing the rights and obligations of partners to one another, but all these rules can be varied or set aside by express agreement. Whether in a particular case there is a partnership or not depends on whether or not the parties intended to be partners, and the question is answered by considering all the terms of the contract, and the conduct of the parties, as a whole. The vital question is, What was the real bargain between the parties? Even if the written agreement says that the relationship is not a partnership, it can still be one in the eyes of the law if the agreement, construed as a whole, gives the rights and imposes the obligations of partnership.

The truth is that if there is a clear agreement between the parties it does not matter much as between themselves whether they are called partners or anything else. If, however, the terms of their bargain are not clear and they appear from all the circumstances to be partners, their rights and duties to one another are fixed by all those provisions of the Partnership Act which they have not agreed to negative or vary. In regard to outside persons, on the other hand, the question of partnership or no partnership is very important indeed, for each member of a partnership is an agent of it, and his acts in the course of business bind the firm; the partners are jointly liable for the firm's debts,* and each is liable civilly, though not criminally, for the wrongful acts of any other in the ordinary course of the firm's business.

THE PARTNERSHIP ACT, 1890

As far as the relations between the partners themselves are concerned the provisions of this Act are binding if they are not clearly varied by the partnership agreement.

* In Scotland each partner singly is liable. The liability of partners to third parties will be discussed more fully later on.

or the conduct of the partners. They create a relationship which is unsatisfactory in the same way that a ready-made suit of clothes is unsatisfactory; it serves its purpose in a rough-and-ready way, but does not really fit. The shortcomings and difficulties of the statutory relationship can be corrected as between the parties by properly drawn articles of partnership, in which the draftsman has tried to anticipate intelligently the difficulties which may arise between partners. In the relations of the partnership with outside people, the provisions of the Act are binding, no matter what arrangements the partners have made between themselves.

If the partners have not agreed otherwise, their rights and duties are as follows. They are all entitled to an equal share in the profits, and must contribute equally towards the losses. The partnership must make good to a partner any payments he has made or personal liabilities he has incurred in the ordinary and proper conduct of the firm's business, or in taking necessary steps to preserve its business or property. Each partner may take part in the management, but no partner is entitled to remuneration for acting in the partnership business. If there are more than two partners, and they disagree on some ordinary matter connected with the business, the decision of the majority will hold good, but an actual change in the nature of the partnership business requires the consent of all the partners.

NEW PARTNERS

No partner may introduce a fresh member into the partnership without the consent of all the other partners. The admission of a partner's son into the business has been held to be an ordinary matter connected with the business, and therefore capable of being decided by a majority (*Highley v. Walker*, 1910). This, however, was an ordinary business partnership: in a medical partnership the personality of the new partner is much more important, and if this factor were made clear to the court it might well decide that the admission of a partner's son was not an ordinary matter, but needed the consent of all the members of the firm.

Partners sometimes agree in their written articles that if one of them wishes to retire, or is incapacitated, or dies, he or his personal representatives (the persons who by law act in his place after death) may introduce a new partner with similar rights and obligations. The remaining partner or partners, having agreed in advance to the admission of the new partner, must admit him. If they refuse, the court may grant an injunction preventing them from excluding the new man; or may order them to render an account (*in Featherstonhaugh v. Turner*, 1858, the representatives were given what would have been the deceased's share of two years' net profits); or may order them to execute the necessary and proper deeds admitting the new man; or may decree a dissolution of the partnership.

In *Byrne v. Reid* (1902) a partner was given the right under the articles to nominate and introduce a son or any other person into the partnership. He nominated a son, whom the other partners refused to admit. The Court of Appeal decided that the son had already become, in equity, a partner, as he had been duly nominated, and the others, although they had not admitted him, ought to have done so. As equity regards a thing as having been done if it ought to have been done, the son was held entitled to have the necessary deeds drawn up.

The court will, in some cases, not be content with allowing damages for breach of contract; it will actually enable the nominee to take his place as a partner. Whether it would treat a medical partnership in this way is doubtful, because the business requires willing co-operation between the partners. It would probably stop short at forcing a new medical partner on an unwilling firm.

EXPULSION OF A PARTNER

No majority of the partners can expel any partner unless they have been given power to do so by express agreement between the partners. Even if they have the power, they must exercise it carefully and in extreme

good faith, for the court is very strict in upholding the rights of the expelled partner, and will at once declare an expulsion void if it considers that the partners have at all failed in their duty or exceeded their power. The excluded partner must be given a full opportunity of stating his case. (These rules do not apply to the right sometimes given by articles to one partner of terminating the partnership if any of the others commits a breach of duty.)

PARTNERSHIP AT WILL

If the time originally fixed for a partnership has expired, but the partners continue to carry on the business without any settlement or liquidation, it is considered in law still to be a partnership on the same terms as before, so far as these are still applicable. The rights and duties of the partners remain the same. Their relationship is, however, now called a "partnership at will," and any partner can instantly dissolve it when he wishes, provided he is acting in good faith and not for the purpose of deriving any undue advantage for himself. There is no expulsion from a partnership at will, whatever the original articles may have laid down. If, however, they contained a provision that, on the death of one partner, the others should buy his interest or admit a nominee in his place, this provision will probably be held to apply to the partnership at will as well as to the original partnership.

GOOD FAITH

Partners must, when required, render true accounts and full information of all things affecting the partnership to any partner or his legal representatives. Moreover, to fulfil the duty which equity lays on all partners of acting in scrupulous good faith to one another, a partner who derives benefit from any transaction concerning the partnership, or from any use of the partnership name or connexion, without the consent of the others, must account to the others for that benefit. This obligation persists even after dissolution by the death of a partner, until the affairs of the partnership have been completely wound up. A partner must not compete with his firm, and a medical partner who, without the consent of the other partners, carried on practice in the district in his own name would have to account for and pay over to the partnership all the profits he made. If he carried on his practice outside the district and not in competition the case might be different, but he would still be using time and effort that he owed to the partnership, and the court might well hold that he was bound to account for his profits. If a partner's appointment expires and he gets it renewed, it is still partnership property, and he cannot profit by it for himself. If he obtains any information in the course of the firm's business he must account to the firm for any profits he may make thereby. If, however, a doctor, using the knowledge he has gained in partnership, writes a textbook, he is doing something which is not within the scope of the partnership's business, and, in the unlikely event of his making any profits, he need not account for them.

Sometimes a partner assigns or mortgages his share in the partnership to secure a debt. In that case the creditor cannot claim to inspect the accounts or to interfere in the management of the partnership, and is entitled only to receive the partner's share. When, however, the partnership is dissolved, he is entitled to the partner's share of the assets, and may claim an account as from the date of the dissolution for the purpose of ascertaining his share.

LIBEL ON LORD HORDER: AN ACTION SETTLED

In the King's Bench Division, before the Lord Chief Justice, on June 29th, a settlement was announced in an action in which Lord Horder claimed damages for a libel in the *Catholic Herald* in June, 1933. Mr. Norman Birkett, K.C., who appeared for the complainant, said that on June 17th last year Lord Horder visited Harrogate to open a sun colonnade. (A report of Lord Horder's speech on that occasion will be found in the *Journal* of June 24th, page 1120.) A local newspaper made him say that facilities for treatment at British

spas were "as good as those at Lourdes," though what he actually said was "as good as those abroad." The late Mr. Charles Diamond, then editor of the *Catholic Herald*, thinking that an attack had been made on the waters of Lourdes, wrote a scurrilous article, with offensive personal references to Lord Horder and to the medical profession, and suggested that Lord Horder, in return for the hospitality of the Harrogate Corporation, was expected to send patients to that spa. The defendants, the New Catholic Press, Ltd., made no attempt to justify the imputations, and now apologized, and expressed their readiness to contribute to the expenses to which Lord Horder had been put. It was stated on their behalf that they were not directly responsible for the words which formed the subject of the complaint. Mr. Diamond, who had since died, was then virtually the owner of the paper, and a man of considerable strength of character. The Lord Chief Justice, in acceding to the settlement, said that it was a grievous thing that a public man like Lord Horder should be attacked in such a way.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The Milk Bill was read a third time in the House of Commons on June 29th. Mr. SKELTON, summing up for the Government, said its proposals for the supply of cheap milk to school children struck into new ground, and focused the attention of the country for the first time on this valuable food. Turning to the provisions for the cleaning up of herds, he contended that these proposals would concentrate the social and economic interests of the community on this.

The Weymouth and Portland Joint Hospital District Bill and the Wycombe and District Joint Hospital District Bill, both of which have passed the House of Lords, were read a second time in the Commons on June 29th and sent to committee.

The Finance Bill was read a second time in the House of Lords on July 3rd.

Debate on Health Estimates

On July 3rd the House of Commons resumed discussion of the vote for the Ministry of Health.

Infant and Maternal Mortality

Mr. RHYNS DAVIES, moving a reduction, asked that the reports and statistics in regard to infantile mortality, which at one time were compiled as between district and district, should be restored. He asked if the Ministry was taking any steps to extend hospital accommodation for the treatment of cancer patients, and to deal with the increase in the number of cases of rheumatism, also what the Minister's policy was in relation to the provision of more maternity homes. In 1934 the grant for the training of midwives and health visitors was £26,500, compared with £27,000 in 1933—a reduction of £500. If money could save the lives of mothers more should be spent. The Minister had had in his department a famous medical woman—Dame Janet Campbell. She resigned a few months ago. Had a successor been appointed? The Minister, in a recent speech, stated that he proposed shortly to issue a circular to local authorities pointing out the directions in which development of their services was still required, particularly in those areas where the rate of maternal mortality was highest. Had that circular been issued, and, if not, when might it be expected?

The Medical View

Sir FRANCIS FREMANTLE said those concerned in the advance that was being made towards the discovery of the causes, prevention, and treatment of cancer were generally of the opinion, though not unanimous, that there was no real increase, age for age and like for like, in the incidence of cancer. As far as they could make out from the actual figures in any one area under like circumstances the total affected of those between 40 and 70 was fairly stationary, although unfortunately it was not being much reduced. The same thing applied to a certain extent to the increase in

rheumatism. There had been a constant decrease in the figures of infant mortality, from 153 per 1,000 seventeen years ago to 62 per 1,000 last year. This drop applied not only to infancy, but was continued through the second, third, fourth, and fifth years of childhood. He would compare the statistics for the years 1911 to 1915 with those for 1932. Taking the mortality in the second, third, fourth, and fifth years of life and comparing it, per 1,000, with the mortality before the war, they found that whereas 35 per 1,000 died in their second year before the war, the figure had been reduced to 14; in the third year of their age it had been reduced from 14 to 6 per 1,000; in the fourth year from 9 to 4 per 1,000; and in the fifth year from 6 to 3 per 1,000. So that in each of the years of the child's life the mortality had been halved in the last twenty years. That was a matter for great satisfaction. Referring to the report of Dame Janet Campbell on maternal mortality in the Netherlands, Sir Francis said that the Netherlands was the only country comparable with ours. Their maternal death rate was lower than ours, but was still increasing, as was ours. He said he would like to see a return to the old system of leaving maternity work in the hands of midwives, bringing the medical man in only as a consultant or in cases of need. In carrying out that idea, it was most important to provide a better training for midwives. With regard to housing, he asked if some of the money that was given for slum clearance could not be used for rehousing tuberculous people in village settlements such as Papworth. Some machinery might also be established between the Minister of Health and the new Unemployment Board, whereby the Minister of Labour might be able to give employment under the Unemployment Act to those who were tuberculous.

Mr. SHAKESPEARE said that it was absurd to say that the condition of the water supply was critical. He denied a statement which recently appeared in a newspaper that because of water shortage there was an outbreak of scarlet fever and diphtheria. When he saw that statement he sent for the best expert in the country, who pointed out that scarlet fever and diphtheria were not diseases associated with the absence of water. With regard to housing, the Government was bringing in a Bill to deal with the troublesome aspects of the problem of overcrowding in London and elsewhere.

Sir HILTON YOUNG, replying to the debate, said that a concession had been arranged in regard to arrears of national health contributions which had not yet been announced to the House. The reduced contribution of 9d. instead of 1s. 6d. hitherto only available to those who had covered three-quarters of the year's contributions, would in future be available to all those who, owing to unemployment, fell into arrears. The cost of the concession would fall on the fund, and ultimately on the Exchequer. To put the country in full possession of the latest position in regard to housing in general and slum clearance, he proposed to make full half-yearly returns. The first would be published after the next September figures. With regard to maternal mortality, the Government's policy was to press ahead with the development and improvement of existing services. It was not content with them, and would not be content until those services under every local authority were in a position as good as the best. He proposed, in the early autumn, when the local authorities were preparing their budgets, to stimulate action by a circular.

Illicit Drug Trade

The 1922 Committee of Conservative M.P.'s was addressed at the House of Commons, on June 25th, by Russell Pasha of the Egyptian Police upon the campaign against the illicit manufacture and smuggling of narcotic drugs. He said that the number of addicts in Egypt had been reduced to one-tenth, and that Governments generally were loyally carrying out the precautions necessary to prevent illicit manufacture and transport of drugs. He praised the work of the Narcotics Bureau at Geneva, but spoke of the manner in which the factories supplying the trade were re-created in new countries, with the most modern equipment after their suppression elsewhere. The center of the trade was now Manchuria, where factories had been established, and the sale of the product in China would give great concern. The most

common drug in the international traffic was now heroin. He had found in the Paris police a disposition not to interfere with the supply of such drugs to "society" addicts.

Training of Nurses in Scotland: Inquiry Committee

Mr. SKELTON informed Mrs. Shaw, on June 26th, that the Secretary of State for Scotland proposed to institute an inquiry into the system of training and registration of nurses in Scotland, and had appointed a Departmental Committee on this subject. The members of the committee would be: Sheriff A. Campbell Black (chairman); Dr. W. L. Burgess, medical officer of health, Dundee; Lady Susan Gilmour, Queen's Institute of District Nursing; Miss M. R. Knight, medical superintendent, Paisley District Asylum; Mr. T. B. M. Lamb, Scottish Education Department; Sir Henry Mechan, Western Infirmary, Glasgow; Mr. John Reid, medical superintendent, County Hospital, Motherwell; Miss Elizabeth Smail, matron, Edinburgh Royal Infirmary; Miss Christina Whyte, matron, Robroyston Hospital, Glasgow; and Dr. John Young, Falkirk and District Royal Infirmary. Mr. W. T. Mercer of the Department of Health for Scotland has been appointed secretary to the committee. The terms of reference of the committee are:

"To inquire into the training and system of registration of nurses in Scotland and to recommend what amendments, if any, should be made in the Nurses Registration (Scotland) Act, 1919, or the rules made thereunder, and what other steps, if any, should be taken to improve the existing system of training and registration."

No Lotteries for British Hospitals

In the House of Commons, on June 27th, the Betting and Lotteries Bill was read a second time after discussion but without a division. While expounding its provisions Sir JOHN GILMOUR said the hospitals throughout the United Kingdom did not desire to enter the field of lottery promotion, since at the present moment they were receiving contributions from every working man in every works and from individuals throughout the country. In these circumstances the Government was right in deciding against the legalization of large-scale lotteries. In closing the debate for the Government Mr. HACKING said that from a motion on the order paper he noticed Sir Wm. Davison had discontinued his demand for hospital lotteries. Those who controlled hospital finances no longer desired this help.

The Bill was referred to a Standing Committee.

Road Traffic Bill Passed

The Road Traffic Bill passed through report stage in the House of Commons on June 28th and 29th. On Clause 13 (payments and insurance in respect of emergency treatment of injuries arising from the use of motor vehicles on roads), a minor amendment was moved and withdrawn, but the matter of the clause was not discussed. The third reading was moved on June 29th after the report stage ended. During discussion Mrs. TATE said she regretted the provision in Clause 13 which made the user of a car liable for payment to doctors for emergency treatment, whether or no the motorist had been in any way responsible for the accident. All sympathized with doctors who were unable to collect their fees; the law was unjust which provided that someone in no way responsible should be penalized. Mr. STANLEY said that since the campaign of propaganda for safety on the roads began in April the figures of fatal accidents had kept level with the totals of last year, although there were about 100,000 more cars on the roads.

The Bill was read a third time.

Unemployment Assistance Board

The Unemployment Act received the Royal Assent on June 29th. On June 30th, in the House of Commons, Mr. RUSSELL MACDONALD announced that Sir Henry Bottomley would be appointed chairman of the Unemployment Assistance Board under Part II of the Act. The Board would also include Sir Ernest Simon, late of the Ministry of Health, Professor H. M. Halliwell, Dr. Thomas Jones, secretary of the Welsh National Campaign against Tubercu-

good faith, for the court is very strict in upholding the rights of the expelled partner, and will at once declare an expulsion void if it considers that the partners have at all failed in their duty or exceeded their power. The excluded partner must be given a full opportunity of stating his case. (These rules do not apply to the right sometimes given by articles to one partner of terminating the partnership if any of the others commits a breach of duty.)

PARTNERSHIP AT WILL

If the time originally fixed for a partnership has expired, but the partners continue to carry on the business without any settlement or liquidation, it is considered in law still to be a partnership on the same terms as before, so far as these are still applicable. The rights and duties of the partners remain the same. Their relationship is, however, now called a "partnership at will," and any partner can instantly dissolve it when he wishes, provided he is acting in good faith and not for the purpose of deriving any undue advantage for himself. There is no expulsion from a partnership at will, whatever the original articles may have laid down. If, however, they contained a provision that, on the death of one partner, the others should buy his interest or admit a nominee in his place, this provision will probably be held to apply to the partnership at will as well as to the original partnership.

GOOD FAITH

Partners must, when required, render true accounts and full information of all things affecting the partnership to any partner or his legal representatives. Moreover, to fulfil the duty which equity lays on all partners of acting in scrupulous good faith to one another, a partner who derives benefit from any transaction concerning the partnership, or from any use of the partnership name or connexion, without the consent of the others, must account to the others for that benefit. This obligation persists even after dissolution by the death of a partner, until the affairs of the partnership have been completely wound up. A partner must not compete with his firm, and a medical partner who, without the consent of the other partners, carried on practice in the district in his own name would have to account for and pay over to the partnership all the profits he made. If he carried on his practice outside the district and not in competition the case might be different, but he would still be using time and effort that he owed to the partnership, and the court might well hold that he was bound to account for his profits. If a partner's appointment expires and he gets it renewed, it is still partnership property, and he cannot profit by it for himself. Lamb, Scottish Education Department; Sir Henry Mechan, Western Infirmary, Glasgow; Mr. John Reid, medical superintendent, County Hospital, Motherwell; Miss Elizabeth Smail, matron, Edinburgh Royal Infirmary; Miss Christina Whyte, matron, Robroyston Hospital, Glasgow; and Dr. John Young, Falkirk and District Royal Infirmary. Mr. W. T. Mercer of the Department of Health for Scotland has been appointed secretary to the committee. The terms of reference of the committee are:

"To inquire into the training and system of registration of nurses in Scotland and to recommend what amendments, if any, should be made in the Nurses Registration (Scotland) Act, 1919, or the rules made thereunder, and what other steps, if any, should be taken to improve the existing system of training and registration."

No Lotteries for British Hospitals

In the House of Commons, on June 27th, the Betting and Lotteries Bill was read a second time after discussion but without a division. While expounding its provisions Sir JOHN GILMOUR said the hospitals throughout the United Kingdom did not desire to enter the field of lottery promotion, since at the present moment they were receiving contributions from every working man in every works and from individuals throughout the country. In these circumstances the Government was right in deciding against the legalization of large-scale lotteries. In closing the debate for the Government Mr. HACKING said that from a motion on the order paper he noticed Sir Wm. Davison had discontinued his demand for hospital lotteries. Those who controlled hospital finances no longer desired this help.

The Bill was referred to a Standing Committee.

Road Traffic Bill Passed

The Road Traffic Bill passed through report stage in the House of Commons on June 28th and 29th. On Clause 13 (payments and insurance in respect of emergency treatment of injuries arising from the use of motor vehicles on roads), a minor amendment was moved and withdrawn, but the matter of the clause was not discussed. The third reading was moved on June 29th after the report stage ended. During discussion Mrs. TATE said she regretted the provision in Clause 13 which made the user of a car liable for payment to doctors for emergency treatment, whether or no the motorist had been in any way responsible for the accident. All sympathized with doctors who were unable to collect their fees; the law was unjust which provided that someone in no way responsible should be penalized. Mr. STANLEY said that since the campaign of propaganda for safety on the roads began in April the figures of fatal accidents had kept level with the totals of last year, although there were about 100,000 more cars on the roads.

The Bill was read a third time.

Unemployment Assistance Board

The Unemployment Act received the Royal Assent on June 29th. On June 30th, in the House of Commons, Mr. RAMSAY MACDONALD announced that Sir Henry Betterton would be appointed chairman of the Unemployment Assistance Board under Part II of the Act. The Board would also include Sir Ernest Strommenger, late of the Ministry of Health; Professor H. M. Hallsworth; Dr. Thomas Jones, secretary of the Welsh National Campaign against Tubercu-

losis, 1910-11, and secretary of the National Health Insurance Commissioners for Wales, 1912-19; Miss Violet Markham, and Mr. M. A. Reynard, a member of the Consultative Committee on Local Health Administration and General Health Questions, 1926-29. Subsequently an announcement was made that Mr. Oliver Stanley succeeded Sir Henry Betterton as Minister of Labour, Mr. Leslie Hore-Belisha becoming Minister of Transport, with other consequential changes in the Government.

Restriction of Immigrant Doctors to Palestine

On July 2nd Colonel WEDGWOOD asked whether, and if so why, new immigrant doctors into Palestine were restricted to five a year, and whether there was a limitation on the number of doctors allowed to practise in any other British Colony or Dominion. He also asked if there were restrictions on the number of Jewish refugees from Germany practising as doctors in Palestine. Sir P. CUNLIFFE-LISTER replied that in March last the Executive of the Jewish Agency in Palestine was informed of a proposal of the Palestine Government to institute measures for the limitation of the number of licences to be issued annually to doctors, dentists, and advocates. No legislation had yet been enacted to give effect to these proposals, which were the subject of correspondence between the High Commissioner and himself. He knew of no similar system of limitation in other British Dependencies or in the self-governing Dominions.

Quinine Stocks of Government of India

On July 2nd the DUCHESS OF ATHOLL asked why the 300,000 lb. of quinine owned by the Government of India were lying idle, for how long had this been the case, and what arrangements were in contemplation for making this stock of quinine available for those who annually suffered from malaria and could not procure it. Sir S. HOARE said that the Government of India habitually maintained a reserve stock of quinine for emergencies. This reserve rose to 300,000 lb. about 1926 and continued at or above that figure until 1932. Measures had since been initiated to reduce it to 150,000 lb., which was regarded as a sufficient reserve. In March, 1933, it had been reduced to 282,759 lb. He had no later figure, but the Government of India was doing its best to increase sales. He would ask for a further report with reference to the last part of the question. The Duchess further asked if the recommendation of the Royal Commission on Agriculture in 1928 that the Government of India should control the production, manufacture, and distribution of quinine in the interests of those who suffered from malaria, had been held up since the first Round Table Conference. Sir Samuel Hoare said there was no foundation for this suggestion.

Contraceptive Advice at Clinics. Replying to Mr. Potter, on June 21st, Sir HILTON YOUNG said he had not made any regulations concerning the giving of contraceptive advice at institutions provided by public authorities, but had indicated the extent to which they were empowered under the statute law to make arrangements for giving such advice. The question of making a charge for any appliances supplied by the local authorities was a matter within their discretion. He had no complete information on this subject.

Physical Training in Scottish Schools.—Replying to Mrs. Shaw, on June 21st, Mr. SKELTON said the number of specialist teachers of physical training employed in State-aided schools in Scotland was 424, of whom 271 were women. Physical training was receiving increased consideration, but he was not convinced it yet occupied in all areas its proper place in the school curriculum, and he would continue to press its claims on the education authorities.

Water Storage Against Drought.—Sir HILTON YOUNG told Mr. Summersby, on June 21st, that large economies in water consumption could be and were being secured without any serious hardship on consumers. With few exceptions, the capacity of storage reservoirs was ample even for dry summers, but storage sufficient to provide unstinted supplies during so exceptional a drought as the present would be very costly, and involve a large permanent increase in the price of water, or a heavy deficiency to be met out of the rates.

Foot-and-Mouth Disease and Animals' Diet.—Dr. ELLIOT, replying to Sir A. Wilson on June 25th, said that it was difficult to summarize the work of the Foot-and-Mouth Disease Research Committee during the last two years. The fifth progress report was in course of preparation, and was expected to be available in the autumn. The Research Committee had considered the possibilities of the connexion between the quality of the food of cattle and the incidence of foot-and-mouth disease, and had advised that there was no evidence to show that diet or hygiene, or a combination of both, had any influence on the spread of the disease. Clinical observations and experimental work carried out by the committee had, in fact, shown that animals in good condition might contract the disease in a more severe form than animals in poor condition. Dr. Elliot also informed Lieut.-Colonel Ackland-Troyte that the conclusions reached by the Departmental Committee on Foot-and-Mouth Disease in 1925 and subsequent experience did not appear to justify further prohibition of the importation of straw, which was already prohibited from countries where foot-and-mouth disease existed.

New Housing Bill for Scotland.—On June 26th Mr. SKELTON told Mr. N. Maclean that the Secretary of State for Scotland proposed to introduce the new Housing Bill for Scotland next session. The object of the Bill would be to stimulate the erection of houses which could be let at rents within the means of people now living in overcrowded conditions who could not afford to pay ordinary rents.

Inoculation of Elementary School Children.—Replying to Mr. Groves on June 27th, Mr. RAMSBOTHAM stated that measures for the inoculation against infectious diseases of children attending public elementary schools were taken by the public health authority and not by the local education authority. The responsibility for obtaining the consent of the parent or guardian did not rest with the education authority. Official memoranda advised that no child should be inoculated without this consent. He had no reason to suppose that this advice was not generally followed. Mr. Groves, on June 27th, drew attention to a remark reported to have been made in a speech to sanitary inspectors by the deputy medical officer of health for Leeds that 8 per cent. of the children inoculated by him with toxoid, with a view to preventing diphtheria, had very severe reactions. Sir HILTON YOUNG said this related only to the use of powerful forms of diphtheria prophylactic employed to induce rapid immunization. The speaker had stressed the importance of applying a preliminary test which would discover the possibly severe reactors, and of immunizing these by the ordinary routine method. Sir Hilton did not think it necessary to ask medical officers of health to report to him all serious results of such inoculations.

Compensation in Cases of Nystagmus.—Sir JOHN GILMOUR told Mr. Tinker on June 28th that nystagmus was not the only injury or disease in view of which employers might be unwilling to take the risk of re-engaging the workman for his old work when he had become physically fit. Whether in such circumstances it was desirable, and in his own interests, that the workman should be entitled to further compensation was by no means simple. Various proposals had been made for modifying the conditions under which compensation was payable for nystagmus, and a full inquiry would be necessary before amending legislation could be considered. If Sir John were satisfied that there was a general demand in the mining industry for an inquiry into this subject he would set up a committee.

Salaries of Civil Servants.—Mr. WILMOT, on July 2nd, asked for a statement as to the intention of the Government on the consolidation of bonus and salary in the Civil Service. Mr. DUFF COOPER replied that the Government had reviewed the position and was satisfied that the proposals made were fair, and that it would be right to put them into operation from July 1st. Detailed instructions would be issued at an early date.

Notes in Brief

Sir HILTON YOUNG has informed Sir Francis Fremantle that the draft of an interim report is now being considered by the Advisory Committee on London Refuse, and that he hoped the committee would be able to complete this report at an early date.

Medical News

The next meeting of the Society for the Study of Inebriety will be held at 11, Chandos Street, W., on Tuesday, July 10th, at 4 p.m., when Dr. John Y. Dent will read a paper on "Apomorphine in the Treatment of Anxiety States, especially Alcoholism."

The Vice-Chancellor of the University of London will present the prizes to students of the London School of Medicine for Women, in the Albert Levy Hall, Royal Free Hospital, on Wednesday, July 11th, at 3.30 p.m. Academic dress will be worn; tea at 4.15.

The Fellowship of Medicine (1, Wimpole Street, W.) has arranged lecture-demonstrations at 11, Chandos Street, W., on July 10th and 17th, at 2.30 p.m.; demonstrations at West End Hospital for Nervous Diseases (in-patient department) on July 10th, at 8.30 p.m.; at 11, Chandos Street, W., July 18th and 19th, at 4.30 p.m.; at National Temperance Hospital, July 14th, at 3 p.m.; courses in urology at All Saints' Hospital from July 9th to 27th; and in dermatology at Blackfriars Skin Hospital from July 9th to 21st. Particulars are given week by week in our *Supplement in the Diary of Post-graduate Courses*.

The director of the Wellcome Archaeological Research Expedition to the Near East announces that the annual exhibition of antiquities from Tell Duweir, Palestine (1933-4 excavations), will be open at 2, Hinde Street, Manchester Square, W., until July 21st from 11 a.m. to 5 p.m. daily, and until 8 p.m. on July 12th and 20th. Admission free without ticket.

A conference on occupational therapy, arranged by the National Council for Mental Hygiene, will be held at 26, Portland Place, W., on Wednesday, July 11th. The afternoon session commences at 2.30 p.m., under the chairmanship of Sir Henry Gauvain, when Dr. J. B. McDougall will speak on "Occupational Therapy and its End-results," and Dr. Veronica Dawkins on "Occupational Therapy, its Possibilities and Limitations in a Sanatorium." Mr. H. J. Seddon will open the discussion on "Occupational Therapy in Relation to Orthopaedic Surgery." At 8.15 p.m., with Dr. Nathan Raw in the chair, Mrs. Eleanor C. Slagle will describe recent methods and advances in America. The discussion will be opened by Dr. J. R. Rees, Dr. Elizabeth Casson, Dr. N. A. Haworth, and Miss Ruth Darwin. Tickets (1s. 6d. for each session or 2s. 6d. for the whole conference) are obtainable from the Secretary, National Council for Mental Hygiene, 78, Chandos House, Palmer Street, S.W.1, or at the doors.

A voyage d'études médicales to the French spas will take place this year in South-East France from September 5th to 16th inclusive, under the conduct of Professor Maurice Villaret, Professor Giraud, Professor Serr, and Dr. Etienne Chabrol. Apart from a visit to the spas in the district, such as Vernet-les-Bains, Luchon, the tour will embrace interesting touring centres like the Gorges du Tarn, Carcassonne, and the Republic of Andorra. Further information may be had from the Federation of the Health Resorts of France, Tavistock House (North), Tavistock Square, W.C.1.

On June 21st Mr. L. G. Brock, chairman of the Board of Control, laid the foundation stone of the Runwell Mental Hospital, which will be shared by the county boroughs of East Ham and Southend, and is designed to accommodate in the first instance 875 patients.

A meeting of the School Medical Service Group will be held at 81, Addison Road, Holland Park, W., on Thursday, July 19th, at 5.15 p.m., when Dr. Gerald Slot will give an address on "Absenteeism in Defective School Children."

The new Queen Victoria Memorial Hospital, Welwyn, will be opened by H.R.H. The Duchess of York on Tuesday, July 24th, at 3 p.m.

Professor G. Grey Turner, Newcastle-upon-Tyne, has been elected a Foreign Honorary Member of the Accademia Lancisiana di Roma.

Councillor and Mrs. W. Barratt have given £20,000 for the erection of a maternity wing at the Northampton General Hospital.

Sir Donald MacAlister, President of the General Medical Council 1904-31, Principal of Glasgow University 1907-29, and afterwards Chancellor, left estate valued at £61,575.

June 26th marked the centenary of the death of Sir Gilbert Blane, author of *Observations on the Diseases of Seamen*, who successfully brought about the disappearance of scurvy from the British Navy by the enforced use of lemon juice.

Mr. Edward William Meyerstein of Dunton Green, Kent, has sent to Prince Arthur of Connaught, chairman of the Middlesex Hospital, a cheque for £70,000 towards the completion of the hospital buildings. He gave £30,000 to the same hospital three months ago.

We much regret to learn, at the moment of going to press, of the death of MADAME CURIE, in a sanatorium in Haute Savoie. The name of Marie Sklodowska Curie, with that of her husband Pierre Curie, who died in 1906, will be for ever associated with the discovery of radium.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62530 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

House Flies

"G. L." writes: From May until the autumn, during the last three or four years, in a house containing nearly forty windows, one single window has been chosen as a promenade by a large number of flies of all sizes; chemical warfare has been waged with paraffin, formalin, camphor, "flit," lavender, citronella, etc., and the windows have been taken out of their frames in order to look for breeding places, but all without success. Can anyone suggest a cause and a lethal permanent cure?

Persistent Epistaxis

"H. H." (Salford) writes with regard to the case mentioned on June 2nd (p. 1015): Might I ask "W. D. C." if haemoplastin (Parke, Davis and Co.) has been tried? Two injections, given close together, followed by others, if necessary, at longer intervals, might quite well cure the condition. Thromboplastin, made by the same firm, is for local application, and would probably be found to be very useful during any attack.

Pruritus with Jaundice

"B. S." writes in reply to the query by "P. J. M." (June 16th, p. 1103): In *Clinical Memoranda*, by Brand and Keith, thyroid extract is recommended to allay the pruritus of jaundice. Of local applications, one of my patients found a solution of Jeyes's fluid most useful, but I had not heard of this possible use of thyroid extract when this patient was ill.

Results of Operations for Elephantiasis

Mr. H. F. BLACKLEE (Barrow-in-Furness) writes in reply to the inquiry by "I. S. Q." (June 30th, p. 1195): May I refer to a case of extreme lymphatic stasis of one lower limb in a young male patient. The condition had persisted since childhood, and had resulted in a huge useless limb, as illustrated in the textbooks of tropical medicine. I performed a Kondoleon operation some four years ago, and the end-result has been highly satisfactory—so much so that last week I met the patient returning from his evening tennis. An especially gratifying feature is the return of soft pliable skin, and also the disappearance of ulcers caused by the pressure of rolls of elephantoid tissue in his original condition.

Exercises for Lumbago

"B. R." (Glasgow) writes in reply to the inquiry by "W. T. H." (p. 1195): Hornibrook's *Culture of the Abdomen* provides several exercises of great value in lumbago. These exercises are meant primarily for the abdominal muscles, but several of them have a marked effect in loosening up the muscles in the lower part of the back. For years I had chronic lumbago, developing severe attacks every few months, and being confined to bed in great pain for several days. I have got almost entirely rid of this trouble, and put my cure down to three things—water, self-massage, and exercises. The self-massage is best done through the pyjamas, using two round-ended rulers. With these a fairly powerful massage can be managed by the patient himself. Water by itself being admittedly an uninteresting drink, I take my extra fluid in the form of weak tea during the afternoon, when I do not eat anything. My experience would go to show that in the cure of chronic lumbago there remain these three things, self-massage, exercise, and water, and the greatest of these is water.

Income Tax**Allowance for Car**

"W. T." purchased a car in April, 1933, for £135, and used it for locumtenent work until September, 1933, when he obtained a resident permanent appointment. The car was wrecked in December, 1933, and the insurance company paid £95. What can he claim?

** (1) Running costs, including licence and insurance, in so far as they were incurred on professional work and were not covered by an allowance received from the practitioner for whom he worked. (2) Depreciation allowance for the six months while he was using the car professionally—that is, 1/2 of 20 per cent. of £135 = £13 10s. With regard to commissions paid to a medical agency for locumtenent work, in our view the earnings of such work are assessable (Schedule D) as professional profits (rather than as emoluments of specific employments), and the deduction of the commission should be allowed.

Payment for Introduction of a Partner

"W. E." asks whether a payment of £50 to a medical transfer agency for the introduction of a partner is an allowable expense.

** No. It is not incurred in the carrying on of the practice, but in connexion with a change—or partial change—in proprietorship, and as such is a "capital" expense.

Fees Paid by Locumtenent

"W. W." asks whether agency fees paid for procuring locumtenent work are deductible.

** We consider that they are deductible. Where they are refused it is usually because the remuneration received is regarded as the earnings of an "employment," and therefore assessable under Schedule E. In our opinion the various earnings are assessable under Schedule D, as the profits of carrying on a profession—the periods of engagement being normally fairly brief—and on that basis the expense is properly allowable, as is also the cost of travelling from place to place while carrying on the profession in that particular way.

Car Transactions—New Practice

"PUZZLED" bought a car for £110 in October, 1931, and commenced to use it professionally on July 1st, 1933, when he entered a G.P. partnership. He sold it in December, 1933, for £40, buying a new car for £127 10s. That car he sold in June, 1934, for £105, and bought another for £140. The first accounts of the new partnership are being made up as for the year to June 30th, 1934.

** On the basis of writing off 20 per cent. on written-down value the original car would be valued at £75 on July 1st, 1933. The replacement allowance would therefore be £75 - £40 = £35 only, and it would seem best to adhere to the alternative depreciation allowance and drop a "renewal" claim. On that basis he should claim:

(a) For the period July 1st, 1933, to April 5th, 1934:

	£	s.	d.
£75 at 20 per cent. for six months ...	7	10	0
£127 10s. at 20 per cent. for three months ...	6	10	0
Total ...	£14	0	0

(b) For the year to April 5th, 1935:

£127 10s. - £6 10s. = £121 at 20 per cent. for three months ...	6	0	0
£140 at 20 per cent. for nine months ...	21	0	0
Total ...	£27	0	0

LETTERS, NOTES, ETC.**The Cancer Problem**

Dr. H. SEARLE BAKER (London, N.3) writes: My attention has been drawn to a letter from Dr. E. F. Hunt in your issue of June 16th (p. 1096). If he will refer to a paper of mine, published in the *Lancet* of September 16th, 1933, he will note that the treatment he advocates has been tried, with results that were definitely encouraging. The method is now being explored intensively, but it is unlikely that any further publication will be made from the purely clinical angle for about a year from now.

Mr. ADAM GOWANS WHYTE (The British Electrical Development Association, 2, Savoy Hill, W.C.2) writes: In your issue of June 16th (p. 1096) Mr. A. W. B. Livesay makes the following observation: "What we want to find is the unknown irritant that is responsible for the abrupt rise in the cancer death rate that occurred in the latter third of the nineteenth century, the time of the introduction of the gas ring and the electric kettle; the rise has continued ever since." I offer no comment upon the suggestion that some connexion may exist between cancer and the boiling of water by one method rather than another, but as a matter of historical fact the electric kettle was a rare phenomenon until the present century, and well on its way.

Asthma in Childhood

"G.P." (Surrey) writes: I have an asthmatic child ephedrine, sodium iodide, and belladonna with excellent results, and I gained great kudos. I did not trouble about a vaccine, as the mother gave me to understand the child was cured. One night the child got another attack of asthma, and the father, with whom I was not very well acquainted, went for another doctor, who gave a vaccine made from the child's sputum, and the child has been in excellent condition ever since. It follows, then, that all drugs are only for temporary use in asthma in children.

The firm of W. Martindale, manufacturing chemists and wholesale druggists, have issued a handy list of their medical products. The booklet is intended primarily for medical men, and any doctor who does not receive a copy by post may have one if he applies to 12, New Cavendish Street, W.1.

The address of the Grenfell Association of Great Britain and Ireland has now been changed to 66, Victoria Street, S.W.1.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 45, 46, 47, 48, 49, 52, 53, and 54 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 24.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JULY 14th, 1934

THE EXAMINATION OF RENAL FUNCTION*

BY

F. S. FOWWEATHER, M.D., M.R.C.P., M.Sc., D.P.H., F.I.C.

READER IN CLINICAL CHEMICAL PATHOLOGY, UNIVERSITY OF LEEDS; CHEMICAL PATHOLOGIST, GENERAL INFIRMARY AT LEEDS

In his presidential address at the opening of this session Dr. G. W. Watson called attention to the large number of laboratory tests that patients are very frequently submitted to nowadays; he considered that many of them were superfluous, and, what was worse, there was a great tendency to allow these tests to take the place of sound, intelligent clinical examination of the patient. I agree with much that he said, but I should like to point out, in the strongest possible terms, that it is not the clinical pathologist who is responsible for this state of affairs, but rather that type of clinician who believes he sees in the clinical laboratory an instrument which can relieve him of much of the work of examination of his patient, and can be made to bear the labour and responsibility of making his diagnosis for him. In this connexion let me quote what I wrote in a little book published in 1928.¹ Other clinical pathologists have written in the same strain.

"The clinical laboratory should never be regarded as an institution which of itself is capable of supplying a diagnosis. It is a means of obtaining additional information about a patient, where it is felt that further information is needed, to add to that already obtained by careful and complete clinical examination. A diagnosis must then be made in the light of all the evidence available. But sound clinical observation is, and must remain, the principal means of arriving at a correct diagnosis. . . .

"The correct attitude of the clinician to laboratory work is that if in any case, after using all the available clinical means at his disposal, he is not thoroughly satisfied concerning the matter in hand, whether it be one of diagnosis, prognosis, or treatment, then he should consider in what way laboratory information may help him, whether to throw further light on a doubtful case, to confirm or negative a probable diagnosis, to decide between alternative views, or in any way to make more certain his knowledge of the matter in hand. This procedure involves the intelligent consideration of the relation of laboratory work to each individual case, and is the reverse of the method of routine application of numerous laboratory tests before a serious attempt is made to consider a case from the clinical standpoint."

The clinical pathologist never intended that his methods and his work should supplant the ordinary methods of clinical examination; but he does believe that, in suitable cases, they supplement these ordinary methods, and frequently add useful information that could not otherwise be obtained.

Acute and Chronic Nephritis

Renal disease is one of the subjects on which information beyond that obtainable by ordinary clinical examination is frequently desired. With regard to acute nephritis, examination of the patient and his urine gives, in the great

majority of cases, sufficient information to establish the diagnosis. (Here I should like to point out that I consider the simpler tests of urine—for example, for albumin, and examination of the centrifuged deposit—as part of the ordinary clinical examination of a patient, and not as special laboratory procedures.) But the matter of prognosis may call for laboratory assistance. There is always the possibility that a case may not recover completely, but that the acute nephritis may become subacute or chronic. Laboratory tests at intervals to show the state of renal function are here very useful, and give the best indication of the progress the patient is making.

So far as chronic nephritis is concerned, laboratory tests may frequently be required to establish the diagnosis: the symptoms may be far from diagnostic; there may only appear to be a general asthenia, or anaemia may be the most outstanding feature; in another case vomiting may be prominent, or headache may be the only symptom complained of. Oedema is, of course, usually absent. The urine, so far as the simpler tests go, may yield little information, for albuminuria is rarely more than slight, and often is absent altogether. Casts, too, are not a constant feature. But careful examination by approved renal function tests frequently makes the diagnosis clear. And in many cases where one feels certain that some renal impairment is present, such tests are useful in giving an indication of the degree of such impairment; for on this point symptoms and physical signs are not always very reliable. We are all familiar with the type of case in which signs and symptoms have appeared relatively slight or almost non-existent until a short time before death has occurred from renal failure.

Blood Urea Concentration

I do not propose to make anything like a complete survey of renal function tests. Many have been tried, but only a few are in anything like general use. Something must be said first about blood urea concentration as an index of renal function.

The important point in this connexion is that a raised blood urea is simply evidence of urea retention; but urea retention is not always due to impaired renal function. Anything tending to produce an oliguria—reduced fluid intake, loss of fluid by vomiting, the formation of effusions, and thus the withdrawal of fluid from the blood—may cause a rise in the blood urea where the kidneys themselves are functionally normal. A similar rise may result from excessive protein intake, or excessive protein metabolism, as in fevers or starvation. If all extrarenal causes can be excluded, then a raised blood urea is evidence of deficient renal function. Any obstruction to urinary outflow also causes urea retention—for example, in enlarged prostate; often the removal of the obstruction

* Delivered to the Leeds and West Riding Medico-Chirurgical Society, April, 1934.

results in a rapid return of the blood urea to normal, and where this occurs we have clear evidence that the urea retention was not due to primary failure on the part of the kidney itself, but to the interference with its normal action caused by back pressure. To the surgeon dealing with this kind of case determination of blood urea at intervals, and, in particular, noting the rate of disappearance of urea retention after removal of obstruction, is a very satisfactory renal function test.

But some impairment of renal function may coexist with absence of urea retention—that is, we may have a normal blood urea in cases in which renal function is deficient. One result of failing function on the part of the kidney is loss of concentrating power, and this occurs in nearly all cases sooner or later. But in earlier stages this failure to produce a concentrated urine may be masked by the ability to produce an abundance of dilute urine, so that actually the normal amount of urea and other waste products is still got rid of, and consequently there is no retention—failure of concentration is compensated for by polyuria.

On account of these limitations on blood urea figures as evidence of the true state of renal function, other tests have been devised in an attempt to obtain a more accurate picture of the real state of affairs, and my chief object now is to describe one of these tests in which I have been particularly interested, and which, so far as my experience goes up to the present, is the best test available.

A Simple Test of Renal Function

But before passing on to describe this I want, briefly, to draw attention to one very simple method of examining renal function which can be carried out with very little equipment or labour, which depends on principles well known to all, but which is generally overlooked.

The test is simply to instruct the patient, while continuing his normal routine, to preserve every specimen of urine passed during a complete twenty-four-hour period, to keep all the specimens separate, and to label each one with the time at which it was passed. At the end of the test he will present you with six or seven specimens. Determine the volume of each and also its urea content, or, failing the latter, the specific gravity is almost as good in nearly all cases; also add the approximate volume per hour for each specimen. Then tabulate the results; they will be somewhat as follows:

A: Normal				B: Nephritic			
Time	Volume	Urea per cent.	Approximate Volume per Hour	Time	Volume	Urea per cent.	Approximate Volume per Hour
11.15 p.m.	—	—	—	11.30 p.m.	—	—	—
7.30 a.m.	390 c.cm.	2.7	47 c.cm.	6.0 a.m.	550 c.cm.	1.4	50 c.cm.
11.10 a.m.	295 c.cm.	1.6	63 c.cm.	10.5 a.m.	350 c.cm.	1.3	84 c.cm.
1.50 p.m.	140 c.cm.	1.8	51 c.cm.	2.0 p.m.	340 c.cm.	1.4	85 c.cm.
4.10 p.m.	110 c.cm.	2.3	47 c.cm.	5.30 p.m.	315 c.cm.	1.5	90 c.cm.
6.0 p.m.	90 c.cm.	1.1	103 c.cm.	8.0 p.m.	210 c.cm.	1.3	84 c.cm.
11.15 p.m.	315 c.cm.	2.0	60 c.cm.	9.55 p.m.	165 c.cm.	1.2	83 c.cm.
				11.30 p.m.	130 c.cm.	1.5	80 c.cm.
Total ..	1,440 c.cm.			Total ...	2,100 c.cm.		

Compare the volume and concentration of the urine secreted during the night with that secreted during the day. Note whether the volumes and concentrations show much or little variation. With normal function the night urine is less in volume, but greater in concentration than the day urine. As the kidneys become inefficient this difference becomes less marked, and as inefficiency advances, the reverse condition begins to appear—the kidneys have to make up during the hours of rest for what they were unable to do during the

period of bodily activity. Throughout the day period, with normal function, individual specimens vary much from one another, the kidneys being quick to respond to changed conditions of waste nitrogen production and fluid intake. With loss of efficiency there is loss of elasticity and ready response to varying conditions—the inefficient organs begin to work at a dead level.

Rate of Urea Clearance

In many cases such a simple test is capable of giving quite useful information. But where its indications are doubtful, or where it is felt that the best available information not only as to the presence but also the degree of functional deficiency is required, other tests are called for, and I want to deal now with the determination of the rate of urea clearance, as a measure of the efficiency of renal function. This conception of rate of urea clearance was introduced by van Slyke and his collaborators, and is dealt with in a series of papers from the end of 1923 onwards.

They had shown that when the urine volume output exceeds about 2 c.cm. per minute (called the augmentation limit) urea excretion proceeds at maximum speed, and the output per minute represents the urea content of a maximum blood volume, which in normal men averages about 75 c.cm. This they termed the maximum blood urea clearance (C_m), or simply the maximum clearance. This is given by the formula

$$C_m = \frac{UV}{B}$$

Where U = urea concentration of urine, B = urea concentration of blood, V = urine volume per minute.

Below the augmentation limit urea excretion is not constant, but varies with the square root of the urine volume. Hence, if we wish to compare urea excretion below the augmentation limit, either we must have a definite standard worked out for every volume below 2 c.cm. that we are likely to encounter, or we must arrange that the subject excretes a fixed volume per minute for which standards are known, or we must be able to calculate from observations for any volume occurring during a given test what would be the clearance if the urine output were a certain definite standard volume. The last is the only practicable procedure, and from observed volumes of U, B, and V it can be shown that the clearance which would occur if the urine volume were 1 c.cm. per minute (called the standard clearance, C_s) is given by the formula

$$C_s = \frac{U}{B} \sqrt{V}$$

The average value of C_s in the normal adult was found to be 54 c.cm.

The results as worked out from these formulae are in cubic centimetres. For clinical work it is much more convenient to have the results expressed as a percentage of average normal function. This can be done if we write the formulae

$$C_m = \frac{100 UV}{75 B}$$

and

$$C_s = \frac{100 U}{54 B} \sqrt{V}$$

Möller, McIntosh, and van Slyke² give line charts which simplify the calculation.

For children, or others whose size differs considerably from that of average adults, a correction is introduced by multiplying the observed V by the factor

$$1.73$$

square metres surface area

Now when renal function becomes inefficient the rate of urea clearance falls below the normal. Hence the determination of the urea clearance will tell us whether renal

function is normal or impaired, and also, where impairment is present, will indicate, at any rate approximately, the degree of impairment that is present.

The test is not difficult to perform. It requires only the determination of the blood urea, the urine urea, and the volume of urine excreted over a known period. It is not necessary to resort to any special preparation of the patient, nor is it necessary to withhold food for some time before the test; vigorous exercise, however, is avoided, and the previous meal should be a moderate one, preferably without coffee. The most desirable time of day is found to be the hours between breakfast and lunch. Moreover, it is not necessary to keep the patient in bed during the test.

In the original van Slyke method urine was collected over two successive hour periods, blood being taken a few minutes before the end of the first hour. The clearance was calculated for each hour period, and, presumably, the average of the two results is taken, though the original paper is not definite on this point. If the urine excreted in the hour period exceeds 2 c.cm. per minute (or if the corrected volume $V \times \frac{1.73}{A}$ exceeds 2 c.cm. per minute in a child) the maximum clearance is calculated; if the urine is less than 2 c.cm. per minute, then the standard clearance is calculated.

Urea Clearance After Dose of Urea

When this work came to my notice I found that I had data from a previous investigation which enabled me to calculate urea clearances not only under conditions similar to those laid down by van Slyke, but also for periods after the patient had taken a 15-gram dose of urea. An important fact which assisted me was that I found the blood urea at the beginning and end of the second hour after this dose of urea to be approximately the same, at an average of about 15 mg. urea nitrogen per 100 c.cm. in excess of the value before urea. The blood

In these tests the students were allowed their ordinary breakfast, except that they were instructed not to take coffee; they were also allowed to carry on their usual activities in the hospital, only interrupting these when it was necessary to come to the laboratory for specimens of blood and urine to be taken. A further series of tests was also carried out on hospital in-patients. Besides being in bed during the test, food had been withheld from the previous evening. Two classes of patients were dealt with—namely, those in whom renal disease was believed to be absent, and those in whom it was believed to be present. The results on the non-nephritic group are in Table I.

TABLE I

Sex	Age	Blood Urea Clearance		Diagnosis
		Before Urea	After Urea	
1 F	32	39	82	Osteitis fibrosa
2 F	47	54	82	Hyperthyroidism
3 M	32	74	83	Nervous vomiting
4 M	45	82	73	Vitreous hæmorrhage
5 F	24	71	95	Cerebral tumour. (Death 16 days later. At necropsy small glioma of sup. corp. quadrigemina found)
6 F	38	55	78	Dyspepsia
7 M	62	90	85	Diabetes.
8 F	54	76	76	Hyperchlorhydria
9 M	35	66	74	Dyspepsia
10 M	47	61	86	Polyarthritis
11 F	—	86	120	Morning vomiting with pregnancy; subsequently cleared up
12 F	—	49	81	Morning vomiting with pregnancy; subsequently cleared up
13 M	63	65	69	Nervous dyspepsia
14 F	28	65	95	Retinitis proliferans
15 F	12	76	76	Delinquency and backwardness; no unhealthy signs apparent
16 F	19	82	85	Fibrositis
17 F	59	28	65	Otosclerosis
18 F	46	48	70	Atrophic gastritis
19 F	50	66	72	Vertigo—(considerable improvement in a few days and patient discharged apparently well)
20 M	26	87	83	Functional albuminuria

Facts Revealed by Test

At this stage it will be convenient to consider some of the facts brought to light by the results so far obtained.

Van Slyke's normal range for Cs, calculated from data obtained from nineteen subjects, some of whom had been examined a number of times, is from 76 to 120. His range for C_m is very similar, and for practical purposes may be considered the same. In my own cases I have made no distinction in the table between C_s and C_m . Actually only a few of the latter occurred.

In the results on students the range before urea is from 29 to 107, while after urea it is 73 to 120.

Of the twenty cases in Table I, seventeen give results, after urea, between 73 and 120 as in the case of students; of the remaining three, two, giving values of 69 and 65, were elderly patients (63 and 59 years respectively), and the third, a patient of 46, gave a value of 70. Before urea the results in these twenty cases lie between 28 and 90.

The great similarity of these results to those on healthy students shows that the difference in conditions observed during the tests has no appreciable effect on the actual results—that is, whether you allow breakfast and mild exercise during the test, or withhold breakfast and keep the patient in bed, does not matter.

The results also make it quite clear that figures, on non-nephritic subjects, obtained without giving urea cover such a wide range as to be really useless as a practical

FIG. 1.—Before urea.

FIG. 2.—After urea.

urea, therefore, during this second hour period is approximately constant (though raised above normal) and a value obtained at any time during this period serves for clearance calculations for the period. On working out clearances before urea and during the second hour period after urea, I found, in persons with presumably normal function, that the values after urea lay within a narrower range than those before urea. It is an obvious advantage to have the normal range as narrow as possible; hence this point seemed worthy of closer investigation under properly controlled conditions, and I therefore made a careful re-examination of the point, using fifty presumably healthy male students as subjects. The results are shown in Figs. 1 and 2.

test; the figures after giving urea, however, do lie within a well-defined range, which can be conveniently used as a standard of comparison. Considering all the results after urea, it seems justifiable to regard the normal value as anything exceeding 70. (The maximum doesn't really matter in this case: it is the minimum that counts.) Some allowance, however, should be made for advancing age, for which a figure of 65 might be taken, from about the end of the sixth decade. Now let us see what results are obtained in patients suffering from renal disease. These are shown in Table II. There

TABLE II

Sex	Age	Blood Urea Clearance		Diagnosis
		Before Urea	After Urea	
1 M	31	42	52	Chronic bone tuberculosis; parenchymatous nephritis. (Subsequently died; at necropsy subacute nephritis; sinus from tuberculous disease of 5th lumbar vertebra and sacro-iliac region)
2 F	23	46	57	Acute nephritis
3 M	36	60 35	48 (23/2/33) 50 (16/3/33)	Albuminuria; oedema— ? subacute nephritis
4 F	17	5.4	6.5	Renal rickets
5 M	17	39	12	Renal rickets
6 F	58	8.7	9.5	Polycystic disease of kidneys
7 M	29	8.4	11.5	Chronic nephritis. (Subsequently died; no necropsy)
8 F	—	22	42	Pregnancy; persistent albuminuria; pyelitis
9 F	47	36	45	? Polycystic disease of kidneys
10 M	34	21	11.2	Chronic interstitial nephritis
11 F	20	25 31	49 (2/1/33) 45 (2/7/33)	Acute nephritis becoming chronic
12 M	25	33	37	Acute exacerbation of chronic nephritis
13 M	35	50	52	Acute nephritis, becoming chronic
14 M	37	41	47	Interstitial nephritis
15 F	29	34	42.5	Pyelitis
16 F	58	53	56	Chronic nephritis
17 F	62	30	9.5	Hypertension; epistaxis. ? Chronic nephritis
18 M	22	58	57	Chronic nephritis
19 F	60	48	52	Granular kidneys; chronic uraemia
20 F	23	31	33	Acute nephritis

is again a difference between the results before and after urea. If we considered the range, on normal patients before urea, of the figures before urea in this table, seventeen would fall within that range. Of the figures after urea, however, the highest is 57—that is, not one falls within the normal range found after urea. This clearly shows that the urea clearance obtained after urea is a better indication of the state of renal function than figures obtained without giving urea; and since it is shown that where renal disease is present figures are obtained which are definitely below what are considered normal, the use of the test for investigating possible departures from the normal is clearly demonstrated.

Technique of Test

The method of carrying out a urea clearance test after urea is as follows:

At 7 a.m. the patient may be allowed a light breakfast; coffee must be avoided, but tea, if weak and in small quantity, may be permitted. At 9 a.m. the bladder is emptied, and immediately afterwards the urea is given. At 10 a.m. the bladder is again emptied. At about 10.45 a.m. a specimen of blood is taken for urea determination, and at 11 a.m. the bladder is once more emptied. The clearance value is of course calculated from data obtained from the

third urine specimen (exact volume, exact time of secretion and urea concentration) and the blood specimen.

These times I have selected as being most suitable for hospital practice; but they can be modified somewhat, so long as the intervals are the same, to suit the convenience of the persons concerned.

Two points are of especial importance—namely, that the bladder must be completely emptied on each occasion urine is passed, and the exact time of secretion represented by each specimen must be known. For the latter purpose it is best to instruct the nurse, or whoever is in charge of the patient during the test, to label each specimen passed with the time to the nearest minute at which it was passed, rather than to insist that specimens shall be taken at exact 60-minute intervals. In the latter case, if, as often happens, the attendant is engaged in some other task when she should be instructing the patient to pass urine, the interval becomes extended to sixty-five or seventy minutes, but she rarely owns up to this, whereas if she is told that a few minutes' variation on either side of the sixty is permissible, so long as the exact time the specimen is passed is recorded, one generally gets more exact data. With an intelligent patient, the requirements of the test can be explained to him, and he will do the time-keeping himself.

Complete emptying of the bladder at the beginning and end of the second hour is, of course, of paramount importance, and this must be carefully explained to the patient. Incomplete emptying of the bladder is, I think, the chief cause of the wide variation of results before urea, for in most cases the volume of urine secreted over the first and second hours after urea is greater than that before urea. At the beginning and end of the second hour, then, there is a more satisfactory stimulus for the bladder to empty itself than when no urea is given. Frequently, in tests of this nature, what occurs immediately before the test is not sufficiently controlled. Thus, a short time before a test begins, a patient may require to empty his bladder. If he does so, when the time for a test specimen arrives the amount of urine secreted during this interval is so small that the impulse to empty is insufficient, and complete emptying does not occur. Or it may be that he is told not to empty his bladder when the impulse arises, but to wait until the test specimen is required. When this time does arrive, over-distension may have occurred, and again we get incomplete emptying. It is for this reason that in the directions for the test I have advised emptying of the bladder at 9 a.m., although it is only the specimen secreted between 10 and 11 a.m. that is really required for the test.

Occasionally one meets with persons who exhibit a psychical inhibition to micturition to order. This occurred twice during my investigation of students—in one case the patient thought he was being overlooked during the act. If the patient is not fussed, rushed, or observed during the act, this difficulty will not often arise. Where retention is believed to be present, or if for any reason it is thought that emptying of the bladder may be incomplete, a catheter should be used.

Advantages of Urea Clearance Test

Having so far described the urea clearance test and its technique, what are its advantages? The greatest appears to be that it takes mathematical account not only of the urea concentration of the blood and urine, but also of the urine volume output. Not only is the ability to excrete urea examined, but the ability to excrete water is also included.

The renal function test hitherto most frequently employed here has been the urea concentration test, together with a blood urea determination. In this test, however, difficulties in interpretation frequently arise when the urine volumes differ greatly from the average, for, although attention is chiefly directed to the urea concentration, the implication of large volumes of urine cannot be entirely ignored; urea is itself a diuretic, and where large volumes of low concentration are obtained, it is frequently impossible to say whether we are to accept this as evidence of a nephritic polyuria, due to loss of concentrating power, or whether we have the

results of a simple diuresis induced by the urea. This difficulty is avoided to some extent by limiting the patient's fluid intake for some hours before the test, but it is not entirely eliminated. No such difficulties arise in the urea clearance test, since volumes as well as urea concentration are taken into account mathematically by the van Slyke formulae.

In all the cases shown in Table II the routine renal function test, consisting of blood urea determination before urea, followed by a urea concentration test, was carried out, in addition to the clearance test already described.

In eight of them this routine test failed to show any impairment of renal function, yet all gave a urea clearance very definitely below the normal range. A careful consideration of all the facts obtainable clearly showed that renal function in these cases was definitely impaired, and left no doubt that the blood urea clearance value is the more correct index of the true state of the kidneys.

I have been making urea clearance determinations for some time now, in all cases where a renal function test has been required, and provided sufficient care and attention are paid to the two points I previously stressed—namely, complete emptying of the bladder and accurate timing of the specimens—I am convinced that the urea clearance is a much better index of the true state of renal function than the test formerly in routine use; I believe it to be, in fact, the best renal function test we possess.

REVIEW OF BLADDER-NECK OBSTRUCTIONS

WITH SPECIAL REFERENCE TO TRANSURETHRAL PROSTATIC RESECTION.*

BY

DUNCAN M. MORISON, M.D., F.R.C.S. ED.

HONORARY UROLOGIST, ROYAL HOSPITAL FOR SICK CHILDREN,
 EDINBURGH, AND DEACONESS HOSPITAL, EDINBURGH

It is perhaps not yet fully appreciated that the symptoms which are regarded as characteristic of an enlarged prostate are common to a number of other causes, not only in elderly men, but in other decades, as well as in the opposite sex. The same symptom group is referred to as diurnal or nocturnal enuresis in the young, frequency in adult life, and prostatism as senility is approached in the male.

The French were probably the first to point out that the urinary difficulties observed in elderly women were similar to those of prostatics, but obviously due to other causes. From the same source we have the term "prostatism sans prostate," when the symptom group is present without any obvious prostatic enlargement being felt per rectum. Accordingly, since this symptom group is common to various ages and both sexes, it is evident that full data should be obtained in each instance before an accurate diagnosis can be given and appropriate treatment instituted. In this paper, however, it has been considered advisable to review only the commoner conditions found in the male, and to exclude malignant disease.

The symptoms referred to are generally a gradually increasing urinary frequency by day and night, the quantities of urine voided at each act becoming smaller. The act may be precipitate, or there may be initial delay; the stream lacking in force and being smaller than normal, it thus takes longer to perform the act, which concludes with dribbling. Variations and additions to the above

will be noted as the individual causal lesions are discussed. This group of symptoms usually indicates some change at the bladder neck which is interfering with the proper emptying of the bladder. To appreciate the various types of obstruction that occur, and the changes they induce, let us briefly refresh our memories with the anatomy and physiology of the parts involved.

Anatomy

The Bladder.—The musculature of the bladder is described as divided into three parts: (a) The walls. (b) The trigone. (c) The vesical neck.

(a) The bladder is lined by a transitional epithelium which is continuous with that of the ureter and the urethra. The wall, aside from this epithelial lining, is made up chiefly of muscle fibres, arranged in an outer longitudinal and an inner circular manner. Because of these acting together on the bladder contents it is better to consider them as one muscle, the "detrusor" of the bladder. Between the musculature and the epithelial lining, or mucosa, is a loose cellular tissue, which is only absent over the trigone. Over the trigone the epithelial lining is firmly attached to the underlying muscle, while in all other portions of the cavity the epithelial lining is so loosely attached to the detrusor that when the organ is empty the epithelial lining falls into folds.

(b) The trigonal muscle develops in the embryo from the muscle layers surrounding the lower ends of the Wolffian ducts and ureters. Later in foetal life these muscles come to lie in the bladder, and their main bundles run from the ureteral orifices to the vesical orifice, where the bundles from the two sides join and run down, just beneath the urethral mucosa on the aspect posterior to and beyond the verumontanum. The upper margin of these bundles passes across from one ureteral orifice to the other, forming a slight elevation—the interureteric ridge—at either end of which the ureteral openings are situated.

(c) The term "neck" of the bladder is employed to designate the region around the vesical orifice. Here the division of the detrusor muscle into two layers is more marked. From each of the two layers, just posterior and lateral to the vesical orifice, is sent a strong band of muscle fibres, which runs down and forward to the prostate to form a loop around the front of the urethra. The bundle from the external longitudinal layer is thicker than that of the internal circular. These together form the "internal sphincter," which is not a circular muscle like the sphincter ani, but only forms an arch around two-thirds of the vesical orifice. The external sphincter is a voluntary muscle, while the "internal sphincter," being supplied by sympathetic and parasympathetic fibres, is an involuntary muscle.

The Prostate.—In the development of the prostate it will be recalled that, in about the twelfth week of foetal life, five groups of tubules grow out from the posterior urethra towards the bladder. At first the five lobes are distinct, but later the two lateral and the middle lobes tend to coalesce. The posterior lobe lying behind the ejaculatory ducts remains distinct. The anterior lobe, which commences by being the same size as the others, retrogresses after four weeks and is completely atrophied before adult life. In a few instances the tubules of the anterior lobe may persist and even be the seat, ultimately, of an enlargement. The lateral lobes, however, are the most active as to growth, and comprise the major portion of the adult prostate.

The Submucous Glands.—Lying under the mucous membrane of the posterior urethra and trigone, and independent of the prostate, are certain accessory glandular structures. They are localized in three situations: (a) the prostatic urethra; (b) the vicinity of the bladder neck; and (c) the trigone. These submucous glands are of importance, since, like the prostatic tubules, they are liable to undergo enlargement in middle and old age, and on account of their situation are likely to give rise to obstruction.

The subcervical group, known also as the glands of Albarran, consist of some thirty branched tubules, whose ducts open into the floor of the urethra proximal to the verumontanum.

The subtrigonal glands lie anywhere between the mid-point of the trigone and the bladder outlet, and are similarly composed of branched tubules. Enlargement of either of these groups may be sufficient to cause typical symptoms of

* Address to Dundee Branch, March 22nd, 1934.

prostatic obstruction, and some authorities maintain that a large percentage of so-called prostatic enlargements are really due to changes in these submucous glands, and not in the actual prostate itself.

Physiology

Considerable attention has been paid recently to the nerve mechanism of the bladder and the various reflexes involved during urination. For present purposes it will be sufficient to gain an impression of the resultant action.

The act of urination is initiated by a contraction of the trigonal muscle, which pulls open the vesical orifice; thereupon the detrusor steadily contracts on the contained urine till the latter is completely expelled. If changes have occurred which make the action of the trigonal muscle difficult its efforts to overcome the difficulty will result in hypertrophy—that is, the trigone becomes raised, the interureteric ridge accentuated, thickened, and approximated to the bladder neck because of the foreshortening associated with a chronic state of undue tonus. If, on the other hand, no impediment exists in the actual opening action of the bladder neck, but some narrowing or obstruction exists distal to the bladder neck, then the detrusor muscle will require to contend with overcoming this difficulty, and in consequence will hypertrophy.

In the relatively earlier stages, accordingly, the site of a lesion may be readily determined on cystoscopic inspection by ascertaining whether the trigone or the detrusor is undergoing hypertrophy. Later, as can be appreciated, both the detrusor and the trigone share in the hypertrophic changes.

Types of Lesions Producing Bladder-neck Obstruction

1. *Congenital*.—This consists of an annular diaphragmatic contracture mainly composed of the mucosal elements, and is morphologically similar to meatal atresia. The unfortunate owner of such a defect may pass into early adult life without appreciating the gravity of his state. The constant and progressive urinary frequency, being regarded as a personal idiosyncrasy, is tolerated till compensation finally breaks down, and medical aid is sought because of impaired health and early uraemic manifestations. On inspection a fully distended bladder is observed, and on further investigation the true cause of the trouble is found. It is probably in this type of case that the prostatic resectoscope achieves the most brilliant results.

There is another form of bladder-neck encroachment which should probably be placed under this category, since it has been observed in young boys—namely, the hypertrophic internal vesical sphincter. Its aetiology is obscure. The musculature of the internal sphincter, particularly that portion which is derived from the circular muscle and occupies the trigonal aspect of the neck, becomes progressively more accentuated, and with any undue stress may enter into acute spasm leading to urinary retention. A course of gradual dilatation with sounds may prove effective, but in marked cases it may be advisable to carry out a partial medial division of the sphincter at the trigonal aspect with a cutting diathermy electrode.

2. *Acquired*.—These comprise: (1) *muscular*, (2) *fibrous*, (3) *submucous adenoma*, and (4) *prostatic adenoma*. For simplicity only four types have been mentioned, and a pure form of each will be briefly discussed. Additional types are frequently cited, but these are usually an admixture of two or more of the above. Congestion, which is a common factor in most bladder-neck lesions, especially the prostatic, will be referred to later.

The muscular type is probably simply a perpetuation of the condition which has already been referred to under congenital. At the same time it can arise from some local irritation, as a ureteritis of the transmurular portion of one or both ureters, or a polyp situated on the verumontanum. The changes observed are similar in

character to that already given. The trigonal portion of the sphincter can be markedly accentuated and raised well above the trigonal level. When unduly stimulated, a degree of spasm may ensue which precludes the proper emptying of the bladder and leads to attacks of urinary retention. The condition is not infrequently met with in highly strung, somewhat neurotic young men. The same treatment is advocated as under the congenital form.

The fibrous type.—This type is secondary to a long-standing inflammatory condition in the posterior urethra, and is usually associated with chronic prostatitis. The interstitial fibrosis commencing in the prostate may extend, not only to the bladder neck, but, since seminal vesiculitis is a common associate, also to the bladder base, impairing the physiological activity of the trigone. The evolution of this type is naturally slow and insidious, and of all forms of bladder-neck obstruction is the one which probably produces the greatest damage to the upper urinary tract. The slowness of its onset permits a more gradual compensation to occur, and extensive renal damage may be present without the individual presenting any obvious indications. In consequence, these cases require far more careful management in preparation for any corrective measures than do the relatively rapidly growing prostatic adenomas.

In the fibrous type symptoms have been present for many years—ten, fifteen, twenty, or longer. They commence insidiously in early adult life, and only become sufficiently marked to bring the individual for medical advice in the fifth to sixth decades. Per rectum the prostate is relatively small, somewhat irregular in contour, and on palpation is firmly elastic with varying areas of density. Tenderness may or may not be increased. Some are definitely hypersensitive. Secretion obtained by massage will usually reveal the presence of pus. On attempting lateral movement the prostate is more fixed in its bed than normal. In a case of marked chronic infection, bands of adhesions may be present, rendering the lateral borders of the prostate less evident.

Cystoscopically, the bladder neck shows a generalized annular contracture; hence the term "sclerosis of the vesical outlet." The secondary changes induced are hypertrophy of the trigone and accentuation of the interureteric ridge, with approximation of this to the bladder neck. The bladder detrusor usually shows some degree of hypertrophy, which in certain instances may be marked, with cellulæ formation and the presence of diverticula. Probably the greatest incidence of diverticula is found in fibrous bladder-neck contractures.

Median bar formation.—The condition which is most commonly referred to as median bar formation appears to be an admixture of the muscular and the fibrous types. In its simplest form this vesical neck obstruction is not associated with any appreciable changes in the prostate. The symptomatology is similar to that of the purely fibrous prostate, but may become sufficiently marked to bring the patient for relief at a somewhat earlier age. The changes at the vesical outlet show, in addition to a general contracture, a definite thickening of the trigonal segment, raising it into a horizontal, well-marked ridge. Histologically this bar presents a fibromuscular stroma which varies as to the percentage of the components. The best form of corrective procedure for the above two types of obstructive lesions is endoscopic resection, whereby a gutter is made in the trigonal portion sufficient to allow proper emptying of the bladder.

Submucous adenoma.—As previously indicated we are indebted to Albarran for differentiating this type from ordinary prostatic lesions. Where rectally the prostate presents no enlargement or adenomatous changes, and cystoscopically an enlarged middle lobe is found, we may presume that the condition is due to the subcervical

group of glands. Alteration of the subtrigonal glands will produce an apparent convex raising up of the trigonal floor adjacent to the outlet, the other findings being the same. A combination of the two groups will lead to a marked, almost polypoidal, projection arising from the trigonal aspect of the outlet. The symptomatology in such cases is of relatively short duration, and occurs more often from the sixth decade onwards, in the usual prostatic period. The situation of the obstruction is such that it very rapidly gives rise to bladder difficulty.

Local inspection will reveal a convex projection arising from the trigonal aspect of the bladder neck, its lateral borders meeting the margin of the outlet at a more or less acute angle to form a "notch." Should any old-standing inflammatory changes be present the angles of incidence will be rounded off into curves. By noting these configurations clinically one can readily arrive at the histological character of the condition present, and be able, by subsequent study of the removed tissue, to confirm the impression gained.

Prostatic adenoma.—The exact aetiology of prostatic adenoma is not yet understood. The lobes chiefly involved are the middle and the two lateral. The anterior lobe, as previously stated, usually atrophies, but may at times persist, and even become the seat of an adenoma. The rate and degree of enlargement in each of the three lobes may be approximately equal, but inequalities occur. Both lateral lobes may hypertrophy in the absence of the middle, and vice versa. One lateral lobe only may show enlargement, but it is more usual to find both involved, though one may be of greater size than the other.

Diagnosis and Treatment

Pending cystoscopic proof of the form of prostatic enlargement present, rectal examination will provide certain indications. If the lateral lobes are equally enlarged and show a definite intervening median furrow, the inference is that there is practically no median lobe present. If both lateral lobes are equally enlarged and the median furrow obliterated and replaced by a continuous convex surface passing from one lateral border of the prostate over to the other, one would anticipate finding an annular type of prostatic enlargement in which all three lobes—middle and two lateral—are practically coalesced, and encircling the bladder neck, with little intravesical projection. Where the upper limits of a prostatic enlargement appear to be somewhat ill-defined, especially at the "notch" in the upper mid-line between the seminal vesicles, one would anticipate finding evidence of intravesical projection with all three lobes contributing their respective convexities.

Cystoscopic examination can be carried out in the majority of prostatites without producing trauma or upset. It should only be done, however, towards the end of the preoperative course of treatment, when the patient is practically ready for operation. The information gained is of the greatest value in determining the mode and type of operative procedure best suited to the local condition present. With a collar type of fused trilobar enlargement there is practically symmetrical encroachment interrupted at 12 o'clock, and also at 5 and 7 o'clock, by notches which indicate the boundaries of the respective lobes. With a trilobar hypertrophy in which the individual lobes are differentiated, the vesical outlet is modified by convex encroachments due to each lateral lobe and the middle, so that the bladder picture is seen, as it were, through a triangular opening.

There is one factor which is important in most prostatic enlargements, and that is *congestion*. It is evident that the presence of a residual urine within the bladder, and the frequent efforts to urinate, will create a state of

congestion. Excessive intake of alcohol, exposure to cold, etc., tends to increase the congestion already present. Prostatic symptomatology does not follow a gradual course of increasing difficulty, as one would expect of a purely mechanical, slowly progressing obstruction. On the other hand, it is notorious how variable the symptoms may be. There may be periods of weeks or days on end with comparative comfort interspersed with corresponding times of marked difficulty. Even during a twenty-four-hour period it is usual to find that the symptoms are more troublesome at night, and that an appreciable initial delay is associated with each urination, and the stream becomes definitely thinner and lacking in force. All these evidences, and more, are indicative of congestion. Indeed, it is the factor of congestion which as a rule ultimately drives a patient to seek relief because of acute retention.

With regard to the treatment of bladder-neck obstructions, I have already suggested endoscopic resection as the operation of choice for several of the lesions discussed. As this type of operative procedure is rapidly gaining ground and being applied to prostatic enlargements with success, I feel that it may be of interest to outline the development of the method. The method has undoubtedly come to stay, but whether it will ultimately displace the open methods of surgical approach to the prostate—suprapubic or perineal—time alone will show.

Transurethral Prostatic Resection

Long before the Christian era instruments had been devised to relieve obstruction to the outflow of the urine, but the actual nature of the obstruction remained obscure.

It was not till 1830 that George Guthrie recognized that, apart from the prostatic enlargement, an equally serious impediment at the neck of the bladder was an elastic bar. He devised a special instrument like a metal prostatic catheter, at the end of which a small knife could be actuated to cut through the bar. In 1874 Bottini introduced his galvanocautery, with which many cases of prostatic enlargement were successfully treated per urethram. Freudenberg improved on Bottini's instrument in 1897 by combining the galvanocautery blade with the irrigating cystoscope, which had now come into use. In 1900 the pathology of the bladder neck was further enhanced by Albarran, who showed that what had been known as the median lobe of the prostate was actually no part of the prostate, but a development at the expense of the glands lying beneath the mucous membrane of the bladder neck, since known as the subcervical glands of Albarran.

From this outstanding contribution investigation by various observers led to the impression that prostatic hypertrophy almost always has its beginning in the subcervical glands, and ultimately involves the vesical sphincter, elevating the floor of the vesical neck, and pushing down the prostate—thus constituting the middle lobe or the horseshoe collar of trilobar adenomatous hypertrophy. Apart from prostatic enlargement, the other main obstructing factor at the bladder neck has received much diverse terminology, and in consequence a corresponding amount of confusion has arisen in referring to this condition in the literature. Among the various names are: median bar formation, the valve at the bladder neck, contracture of the vesical neck, median lobe hypertrophy, atrophy of the prostate, submucous fibrosis of the bladder neck, "prostatisme sans prostate," sclerosis or atony of the vesical orifice, musculo-glandular hypertrophy, hypertrophy of Albarran's subcervical glands, hypertrophy of the subtrigonal glands, aberrant or isolated median lobe prostatic hypertrophy, "maladie du col vesical," etc. All these indicate the horizontal median bar of hyperplastic tissue which contains all the elements of the vesical neck.

Types of Instrument Used

The present development of transurethral methods undoubtedly owes its inception to Hugh Young of Baltimore, who in 1909 described a "punch operation" for removal of the median bar by means of a modified endoscope. The method became widely used, but had drawbacks in that the actual cut was made blindly, and serious haemorrhage was not infrequently to be contended with. In the same year Beer of New York applied the Oudin monopolar current for the destruction of villous growths in the bladder, by employing a heavily insulated copper electrode through an ordinary catheterizing cystoscope. The procedure was a complete innovation and came to be known as "fulguration." Three years later—that is, in 1913—Stevens and Bugbee, working independently, reported cases in which they had applied fulguration to certain bladder-neck lesions, including enlarged middle prostatic lobes, with eminently satisfactory results. Luys of Paris soon followed with a similar procedure, which he termed "forage de la prostate." In 1920, Caulk of St. Louis evolved a cautery punch with which obstructing fibrous bars or small middle lobes could be removed under vision and without haemorrhage. This instrument with modifications has for some time now been extended by Caulk for the resection of enlarged prostates. Caulk claims that, after all obstructing portions of tissue at the bladder neck have been removed, and an adequate fresh channel is established, the prostate shrinks considerably in size. Although immediate post-operative bleeding is obviated, this instrument is apt to produce late haemorrhage when the slough comes away one or two weeks after operation. Further, the procedure tends to be followed by a rather high incidence of secondary infection. Kenneth Walker of London introduced in 1925 an ingenious diathermy punch, which, though proving extremely efficacious in certain forms of median bar formation, was yet difficult of application to others.

A fresh impetus was given to transurethral surgery in 1926, when Maximilian Stern presented his "resectoscope." In describing this new instrument he said:

"It has become possible to reduce the problem to a mere cystoscopic procedure by the evolution of a cutting current capable of operating in a water medium, and a cystoscopic instrument for its application. This instrument is provided with a small movable ring or loop of tungsten wire which, when actuated by a suitable current, is capable of removing longitudinal spaghetti-like sections of tissue. The former of these instruments I have named the 'resectotherm' and the latter the 'resectoscope.'"

The principle of Stern's instrument has since been applied to a number of electrotomes, each of which has been specially modified according to the ideas of individual urologists both in America and in Europe. Probably that of McCarthy of New York is as widely used as any. The claims for McCarthy's instrument are:

- (a) Accurate visualization of the prostatic urethra.
- (b) Greatest possible flexibility of manipulation, under vision, of the cutting loop.
- (c) Ample electrical power to excise the obstructing prostate under water, with a coincidental minimum of haemorrhage and of tissue coagulation.
- (d) Ease of interchange of electrodes for the closure of bleeding points.
- (e) At the completion of the operation, a No. F24 whistle-tipped indwelling catheter can be introduced through the sheath, before the latter is withdrawn: a definite time-saving and trauma-reducing procedure.
- (f) Rapid epithelialization with a minimum of cicatrization. The cutting electrical current employed is from a vacuum tube generator which gives 2,000,000 oscillations per second.

Advantages of Transurethral Operation

The transurethral route has proved itself the method of choice in dealing with congenital and acquired contractures of the vesical outlet. It is only comparatively recently, with the introduction of more efficient apparatus, that enlargements of the prostate have been treated by this means. Criticism naturally attends every new departure, and time alone will allow a proper perspective. Transurethral prostatic resection aims at re-establishing an adequate outflow from the bladder, without attempting to remove as much prostatic tissue as possible. The so-called radical operation of "prostatectomy" shells out only the adenoma, leaving behind a displaced capsule of prostatic tissue—from which, not infrequently, and if the patient lives long enough, fresh adenomata will develop. The open operation in a non-infected adenomatous case is extremely simple and leaves behind a clean prostatic bed, which on resolution provides a smooth channel and an excellent result.

Where chronic inflammatory reaction has been present prior to the development of adenomata the shelling out of the prostate is far from simple. We are all too familiar with the laborious effort entailed in such cases, an effort which is rewarded by the removal of fragmentary portions of dense tissue at the expense of bleeding and trauma with consequent shock. The degree of manipulation necessary tends to traumatize the prostatic venous plexus and invite the subsequent formation of thrombi. The convalescence in this type of case is, more frequently than not, a stormy one, and the after-result as regards the condition of bladder neck and posterior urethra in many instances such that the patient continues to have dysuria and frequency. In dealing with this particular type of prostatic lesion, accordingly, one cannot but feel that the resectoscope offers in competent hands a safer procedure at the time, and a better after-result than can be accomplished by the open route.

Each prostate case should be subjected to a careful routine examination, both general and local, and the exact form of bladder-neck obstruction determined by cystoscopy where possible. Infection, when present, should be corrected, and the congestion which is almost an invariable associate allowed to settle by appropriate means before any operative measures are contemplated. The mortality of prostatectomy has been reduced during the last twenty years mainly through more careful pre-operative care. With the application of transurethral methods there was a tendency at first to pay less attention to preoperative management, but it was soon revealed that as much care is necessary as when contemplating the open operation.

The technicalities of prostatic resection need not be entered into here, but there are a few points which may be mentioned. The procedure is relatively simple. The field of operation is visualized throughout the entire period. The altered bladder neck is trimmed down step by step till a clear channel extends from the trigonal floor down to the upper aspect of the verumontanum. It is wiser, in the interests of an enfeebled patient, not to attempt to remove too much tissue at one sitting, but to conclude after the main obstructing portion has been dealt with. The more raw surface exposed, the more is absorption likely to take place. Further, as the cutting loop of the electrode enters deeper planes, some bleeding is apt to be induced which may take longer than anticipated to stop. It must be remembered also that the electrodes generate heat, and the more cuts made the greater will the tissue be heated up, thus encouraging ultimate slough formation, and possibly secondary haemorrhage. It is evident that if, instead of one operation which might endanger life, the process can be

conveniently subdivided into two or three, carried out without any undue risk, the latter course is to be preferred.

After-treatment

The procedure following transurethral resection is that a retention catheter is left in for two to three days. After its removal the patient can get up, and is able to void as required. At first, owing to reaction oedema, the voidings may not be complete, and it is as well in such cases to carry out intermittent catheterization morning and evening, instilling argyrol or silver nitrate solution after the bladder is empty and before removing the catheter. This may require to be done for four to five days, after which the patient can return home. As a rule a period of a week to ten days is sufficient for the post-operative course. For debilitated, senile patients, a longer period under supervision is advisable. In cases of fibrous prostate with long-standing contracture of the vesical outlet, the bladder tone is usually much impaired, and although a free outflow has been established, some time may elapse before the detrusor tone is sufficiently established to effect complete emptying of the bladder. In such cases silver nitrate irrigations have proved of the greatest value.

A repeat operation, if the primary procedure has not come up to expectations, should not be considered until all immediate local reaction has settled and the prostate has had some time to shrink. Reinspection of the operative field after three weeks will reveal complete epithelialization, and as a rule no trace of sloughs. Each case, however, should be individually judged as to the general as well as to the local condition, before further intervention is deemed advisable. A repeat operation is invariably easier to perform and necessitates a much shorter period of care, since no further course of preoperative preparation is called for. If the procedure is carried out as above outlined there is no operative shock, and no subsequent pain, nor is the patient confined to bed for longer than a period of three to four days throughout the entire course of corrective treatment.

Conclusion

The laity tends to think that any operation carried out after the age of 60 is a "do or die" performance, but it is the duty of the profession and of science to minimize risk and prolong life. It is because such a forlorn view of prostatectomy is taken by the majority of people—including some members of the medical profession—that victims of prostatism carry on with their complaint till finally an acute obstruction brings them suddenly face to face with the fact that at last something has to be done, and they are by this time reconciled to the worst. It is just this aspect of prostatic and bladder-neck trouble which one would like to emphasize. Why allow a patient to go on with obstructive urinary symptoms till the prostate is sufficiently ripened to permit of enucleation, when all the time progressive renal impairment is taking place, and the patient's general system is becoming more toxic and less able for surgical intervention?

Now that we have the means of determining and correcting such troubles, even in their incipient stages, is it not in the interests of common sense and the community at large, that these individuals be immediately attended to, and saved unnecessary years of suffering and impairment?

It has been said: "The surgery of the obstructing prostate of to-day involves an appreciation of the necessity of its early recognition as well as its prompt correction when the patient shows his greatest credit balance in resilient arteries and other physical assets, and before he has got well along the inevitable road to material depreciation of those assets. Moreover, he can and should have this journey made easier and the road longer."

HIGH CARBOHYDRATE DIETS AND INSULIN EFFICIENCY

BY

H. P. HIMSWORTH, M.D., M.R.C.P.

BEIT MEMORIAL RESEARCH FELLOW; ASSISTANT, MEDICAL UNIT,
UNIVERSITY COLLEGE HOSPITAL, LONDON

During the last four years the use of diets containing a relatively large quantity of carbohydrate has become more and more common in the treatment of diabetes mellitus. When these diets were first introduced they were received with many theoretical objections, but their undeniable success rapidly compelled their serious consideration and encouraged their increasing acceptance. This divergence between theoretical objection and practical success is no minor discrepancy capable of easy adjustment after careful revision of the data, but a definite conflict between two diametrically opposed conclusions. On the one hand, a well-founded theory directs that the carbohydrates in the diabetic's diet must be curtailed if health is to be preserved; whilst, on the other, a brilliant piece of clinical empiricism produces irrefutable proof that a liberal allowance of carbohydrate acts favourably on the diabetic's health. At present it may be said that the theoretical objections are securely established, not only on a logical sequence of experimental results, but also on the accumulated clinical experience of diabetes mellitus before the introduction of insulin; whilst the beneficial effects attending the use of high carbohydrate diets are inexplicable either by any known physiological or pathological mechanism, or on the basis of previous clinical experience. A probable clue as to the nature of the discrepancy is suggested by a consideration of the chronological relation of the conflicting views.

The good results following the use of high carbohydrate diets were not discovered until after the introduction of insulin treatment. This suggests that there exists in the body a mechanism capable of stimulating the utilization of carbohydrate, but which cannot exert its action in the absence of an adequate supply of insulin. It was with the object of searching for this mechanism that the present work was undertaken, and the employment of healthy men as subjects for the search was dictated by the supposition that it would only be possible to detect the unknown mechanism in subjects possessing the normal supply of insulin.

Theoretical Objections to High Carbohydrate Diet

Before discussing the present research it is first necessary to glance at the work upon which the theoretical objections to the use of high carbohydrate diets in diabetes are based. For a long time it has been known that the excessive consumption of carbohydrate by the diabetic results in deterioration of his clinical condition. It was not, however, until a few years before the discovery of insulin that light was thrown, by the work of F. M. Allen and his collaborators, on the mechanism of this unfavourable clinical change. Allen studied the effect of diet upon the health of partially depancreatized dogs, and summed up his results by saying:

"Dogs which have lost a certain amount of pancreatic tissue will become diabetic irrespective of diet. Dogs which retain a sufficient amount of pancreatic tissue will never become diabetic irrespective of diet. But between these two groups is an intermediate group. On an Eskimo diet they may be found to live in health. On a Hindu diet they soon go down to fatal diabetes."

Thus if sufficient pancreas is removed from a dog so that it is on the borderline of pancreatic diabetes the animal lives, if it receives a low carbohydrate diet, and the blood sugar remains low and glycosuria does not occur. But if such an animal is given a diet rich in

carbohydrates the full clinical and chemical picture of pancreatic diabetes appears, and the animal rapidly dies. Allen further confirmed the work of other investigators, showing that, as a general rule, once pancreatic diabetes has been induced in these dogs by excessive intake of carbohydrates, then a return to the low carbohydrate diet will not cure the condition. It would appear that ingestion of excess of carbohydrate overstrained the remaining pancreatic tissue so as to produce a permanent degree of degeneration.

In the partially depancreatized dogs which died of the diabetes thus induced, histological examination of their pancreatic tissue revealed hydropic degeneration of the β cells of the islets of Langerhans, and Allen emphasized that this was also found in the pancreas of the patient dying in diabetic coma. As by this time the probability of the insular tissue's secreting an "anti-diabetic hormone" was generally accepted, conclusions from Allen's work were easily drawn. In the partially depancreatized dog excess of dietary carbohydrate, by producing a raised blood sugar, causes overstrain of the islets in the remaining pancreatic tissue; under this strain the cells break down and eventually are unable to secrete sufficient hormone to prevent the development of pancreatic diabetes. At death the β cells of the islets are in a state of hydropic degeneration; the pancreas from the diabetic dead of his disease shows similar lesions; therefore to preserve life in the diabetic the islet cells must be guarded against overstrain by maintaining the blood sugar at a low level by restriction of carbohydrates in the diet. The Allen diet—and the theoretical objections—are based on these conclusions.

Practical Experience

On its first introduction insulin was given merely as an adjunct to the Allen diet, but as its use became more widespread it began to be employed in conjunction with diets containing larger and larger quantities of carbohydrate, until the present high carbohydrate diet was evolved. It had been logically assumed that, in the diabetic needing insulin, increase of carbohydrate in the diet would necessitate an increase in the insulin dosage. But this assumption was speedily found to be false. Not only did the diabetic not require a proportionate increase of insulin for each extra gram of carbohydrate included in his diet, but his insulin requirement often remained unchanged. For example, if a patient is balanced on a diet containing carbohydrate 50 grams, protein 80 grams, and fat 115 grams and is then changed straight over to one containing carbohydrate 120 grams, protein 80 grams, and fat 76 grams, in the majority of cases no increase of insulin will be necessary. According to the current theory the excess of carbohydrate in the second over the first diet should produce the insulin requisite for its utilization by "flogging" the diabetic's already diseased islets, and the result should be rapid deterioration of the clinical condition. But the clinical condition does not deteriorate. On the contrary, the patient feels and continues to be much improved.

The only explanation so far offered of this striking paradox is on the basis of Allen's experiments on the glucose equivalent of insulin.⁴ Working with depancreatized dogs, an attempt was made to determine how many grams of carbohydrate each unit of insulin would cause to be retained in the body. It was speedily found that there was no direct linear relation between the carbohydrate eaten and the dose of insulin needed to prevent glycosuria, and Allen arrived at the conclusion that the more carbohydrate ingested the less is the insulin required to metabolize each gram. It will be seen that this work provides no real explanation of the clinical problem, but only restates it in a different form.

The Staub-Traugott Phenomenon

Up to the present the masterly work of Allen and his collaborators has dominated the conception of diabetes mellitus, but recently another line of research has begun to turn thought in a different direction. In 1919 Hamman and Hirschman⁵ described the phenomenon which is now usually referred to as the Staub-Traugott effect. They showed that if two consecutive doses of glucose are given to a healthy subject the hyperglycaemia resulting from the second dose is lower than that after the first. The current explanation of this phenomenon (Macleod)⁶ is that the first dose of glucose sensitizes the insulin-secreting mechanism, so that in response to the second dose the islet cells secrete insulin more readily and more abundantly at a lower level of hyperglycaemia. On the basis of this explanation Sweeney,⁷ in 1927, attempted to explain the variations in sugar tolerance found in normal subjects on different diets. Using the ordinary glucose tolerance test as a guide, he investigated the sugar tolerance of healthy individuals during starvation, on a fat diet, on a protein diet, and on a carbohydrate diet. He found that protein had little effect; that fat diets and starvation diminished sugar tolerance; and that carbohydrate diets improved sugar tolerance. Sweeney considered that the diminished sugar tolerance was due to the impaired sensitivity of the insulin-secreting apparatus, consequent upon the absence of the stimulus of carbohydrate ingestion, and that the improved tolerance was the result of the increased sensitivity of this mechanism, owing to greater stimulation.

Effect of Diet on Insulin Action

All the work we have considered so far has dealt with the influence of diet only upon either normal or abnormal carbohydrate tolerance. It is surprising that little attention has been paid to the effect of diet upon the action of insulin itself. A few papers, however, have appeared. Bainbridge⁸ and Hynd and Rotter⁹ showed that animals convulsed earlier after injection of insulin on a carbohydrate than on a fat diet. It appeared to me that a key to the problem of the influence of diet upon the healthy subject's sugar tolerance lay in a possible relation between the organism's tolerance for sugar and its sensitivity to insulin. If it were found that high carbohydrate diets, which improve sugar tolerance, sensitized the subject to insulin, then the effect of diet upon insulin action would have been established, and the observation that many diabetics need no more insulin on the high carbohydrate than on the low carbohydrate diet could be explained on these lines. It was accordingly determined to investigate the result of different dietetic conditions, both on sugar tolerance and on sensitivity to insulin, with a view to discovering whether a correlation existed between the two phenomena.

Methods Employed

For the purpose of this investigation healthy young men were used. They varied in age from 18 to 22 years, and as far as could be ascertained they had never suffered from any serious illness and were in perfect health during the experimental period. They were admitted to the ordinary ward of the hospital and underwent the usual routine of hospital patients, save that they were allowed up during the morning and afternoon. The special diet allotted to them was prepared and weighed in the diet kitchen of the hospital, and its consumption was checked by the ward sister. There was no reason to suspect that any of them surreptitiously supplemented his diet in any way. No experiment was carried out until the specified diet had been given for one week, and only one experiment was performed on the same day. On the day before an experiment the subject retired to bed at 6.30 p.m., and remained there (without breakfast) until 9.30.

a.m. the next day. He then went to the laboratory adjoining the ward and was allowed to rest for half an hour: the experiment commenced promptly at 10 o'clock. During the whole of the subsequent procedures the patient remained at rest in an easy-chair, and precautions were taken to keep him comfortably warm. Blood specimens were taken from the ear, and the blood sugar was estimated by the Hagedorn-Jensen method.

For the glucose-tolerance curves three blood samples were taken in the resting state; 50 grams of glucose in 300 c.cm. of cold water flavoured with citric acid and essence of lemon were given by mouth, and blood samples were then taken every ten minutes for three hours.

For the curves following injection of insulin—insulin depression curves—four blood samples were collected in the resting state; 5 units of a solution of crystalline insulin were injected intravenously, and blood samples were collected, first, every two minutes, and, later, every three minutes, for thirty-five minutes. The technique for obtaining satisfactory blood samples with this frequency necessitated the training of a team of assistants, and the test is for this reason impracticable outside an experimental laboratory. It was necessary to use a solution of crystalline insulin, as commercial insulin contains an impurity which, on intravenous injection, causes a transient but variable degree of hyperglycaemia.

Results

In Fig. 1 two glucose-tolerance curves in the same subject are represented—the one (high fat diet) on a low-carbohydrate-high-fat diet; the other (high carbohydrate diet) on a high-

FIG. 1.—Two sugar-tolerance curves after 50 grams glucose; both obtained on the same healthy subject. The upper one was obtained when the subject was taking a high fat diet, the lower when he was taking an equicaloric high carbohydrate diet.

carbohydrate-low-fat diet. Both diets were of the same total calorie value. It will be seen that on the high fat diet the sugar tolerance was diminished, as indicated by a high degree of hyperglycaemia after glucose; whilst on the high carbohydrate diet the glucose tolerance was raised, as demonstrated by the low hyperglycaemia after oral glucose.

Fig. 2 shows two insulin depression curves, one being obtained on a high fat diet and the other on an equicaloric high carbohydrate diet. It is evident that on the high fat diet insulin takes longer to act, and then acts more slowly, on the blood sugar than when the subject is given a high carbohydrate diet.

These two results are examples of a wide range of experiments on healthy men⁸ and animals⁹ which I have presented elsewhere, and it may be stated as a general rule that those dietetic conditions which bring about improvement of sugar tolerance are always associated with an increased susceptibility of the organism to insulin, whilst those which cause impairment of sugar tolerance are invariably accompanied by a decreased susceptibility.

Another method for improving the sugar tolerance is that exemplified in the Staub-Traugott phenomenon. One dose of glucose will lessen the hyperglycaemia resulting from a second dose; the latter, in turn, will diminish the hyperglycaemia from a third dose. Subjects habituated to a specified diet were therefore selected, and the rate at which insulin depressed the blood sugar was determined. Some days later, to the

same subject, 50 grams of glucose were given, and one hour after the resulting hyperglycaemia had completely subsided the standard dose of insulin was injected and the rate of depression of the blood sugar again estimated. After glucose the blood sugar with insulin sank much more rapidly than in the fasting state; the administration of the preceding dose of

FIG. 2.—Two insulin depression curves after 5 units of crystalline insulin solution intravenously; both obtained on the same healthy subject. The upper one was taken during the high fat regime, the lower when he was taking an equicaloric high carbohydrate diet.

glucose had caused, in the subject, the development of a state of increased susceptibility to insulin. This experimental observation merits further consideration.

Discussion of Experimental Findings

Zunz and la Barre¹⁰ have demonstrated that a rise of blood sugar induces secretion of insulin by the pancreas. In the Staub-Traugott experiment the first dose of glucose brings about this secretion of insulin, but, as I have demonstrated, it also gives rise to a state of increased susceptibility to insulin. With the second dose the hyperglycaemia again calls forth the secretion of pancreatic insulin, but, the animal being now more susceptible, less insulin is required to reduce the hyperglycaemia to the normal level of blood sugar. Thus to explain the Staub-Traugott effect there is no necessity to postulate that glucose ingestion results in an increasing sensitivity of the insulin-secreting mechanism, for even if the same amount of insulin is secreted in response to each dose of glucose the consecutive improvements in tolerance can be adequately explained by the experimental observation of the progressively increasing susceptibility of the organism to insulin.

Now the maintenance of the blood sugar at normal levels is largely dependent upon the secretion of pancreatic insulin. This has recently been proved very beautifully by Gayet,¹¹ who has shown that when the pancreas is cut out of the circulation the blood sugar begins to rise; when its circulation is restored the blood sugar returns to, and remains constant at, the normal level. Consider the normal subject in the basal state. To maintain the blood sugar constant at the fasting value a certain output of insulin from the pancreas is necessary: 50 grams of glucose are now given, the hyperglycaemia is allowed to subside, and the blood sugar comes to rest within a few milligrams per 100 c.cm. of the fasting level. But we know by experiment that the subject is now more susceptible to insulin, and therefore the pancreas must be putting out less insulin than it did in the fasting state; otherwise the blood sugar would tend to hypoglycaemic levels. If the procedure is repeated we shall find that, after a further dose of glucose, when the blood sugar has returned to resting levels the animal is still more susceptible to insulin, and therefore the secretion of insulin from the pancreas must be still further reduced.

We thus arrive at the conclusion that the progressive diminution of hyperglycaemia in consecutive glucose-tolerance curves is due to the progressively increasing susceptibility of the subject to insulin, this increase being so marked that an actual decrease in the output of pancreatic insulin would appear to accompany the improving tolerance. From these considerations the explanation of the improved tolerance found in a normal subject on a high carbohydrate diet becomes clear. *The increased tolerance is due to the organism's increased susceptibility to its own insulin.* Similarly, the diminished tolerance seen in starvation and in subjects receiving a low-carbohydrate-high-fat diet is owing to their lessened susceptibility to their pancreatic insulin. Further, we have brought forward results⁹ which show that the ability of an animal to develop an increasing susceptibility to insulin after administration of carbohydrate is influenced by the diet which it is receiving. A carbohydrate diet facilitates the development; a fat diet retards it.

It must be remembered, however, that we have not demonstrated whether the heightened susceptibility seen on the carbohydrate diet is the result of the excess of carbohydrate or of the restriction of fat in the diet, and, similarly, whether the lowered susceptibility on the high fat diet is the outcome of the restriction of carbohydrate or the excess of fat in the diet. It is possible that in the removal of the blood sugar some factor other than insulin is concerned—an unknown factor which governs the susceptibility of the animal to insulin. As to the nature of the unknown factor we have no information. It seems to be intimately connected with insulin action. There are two simple possibilities. The factor may be an inhibitor of insulin and its production be inversely proportional to the carbohydrate content of the diet; or it may be an activator of insulin, whose production is directly proportional to this content. On evidence brought forward elsewhere^{8, 12} I incline to the activator hypothesis.

Clinical Significance of the Results

The results recorded in this paper carry us some way towards the explanation of Allen's glucose equivalent of insulin. The reason behind the observation that the more carbohydrate ingested the greater the amount retained in the body by each unit of insulin is that the more carbohydrate eaten the more sensitive the organism becomes to each unit. Hence the paradox of the glucose-insulin equivalent. It will be remembered that Allen's experiments were carried out on depancreatized dogs, and thus demonstrate that such a dog under the stimulus of the administration of carbohydrate is capable of developing an increasing sensitivity to insulin.

My results show that the giving of carbohydrate raises the efficiency of both injected and pancreatic insulin in the normal subject. It only remains to prove that carbohydrate has the same action in the diabetic and the explanation of the beneficial effect of high carbohydrate diets in these patients has been achieved. Ellis¹³ has recently supplied this proof. To diabetics needing large doses of insulin he gave glucose by mouth and small doses of insulin every hour. A remarkable increase in insulin efficiency resulted. Despite the ingestion of constant large amounts of glucose the dose of insulin required to restrain the blood sugar within normal limits decreased progressively. These results show that some diabetics, though possibly not all, are capable of developing a heightened sensitivity to insulin under the stimulus of carbohydrate ingestion. Thus the improvement of diabetic patients on a high carbohydrate diet is to be ascribed not to the greater stimulation, and consequent overstrain, of their insulin-secreting tissue by the excessive

intake of carbohydrate, but rather to the rendering of the diabetic more susceptible both to his pancreatic and the injected insulin. The result is that each unit of insulin available accounts for a greater amount of carbohydrate. This, necessarily, by allowing a more economical utilization of the insulin secreted, reduces the demand of the body for insulin, with a consequent easing of the strain on the diseased islet cells. By thus lightening the burden on the cells which remain capable of function it is possible that we aid their conservation as healthy tissue, and save rather than squander the patient's own pancreatic resources.

If the augmentation of a diabetic's sensitivity to insulin is of importance in the balanced state, it is of much greater importance in the state of coma. It is well known that hundreds of units of insulin may be given in this condition with little effect on the blood sugar, when in the same diabetic after recovery 20 or 30 units will produce hypoglycaemic symptoms. Many comatose and precomatose patients seem to be relatively insensitive to insulin, and any measure directed to raise their sensitivity would appear to be of benefit. To this end glucose should be administered in large doses. The success of treatment based on this principle I have recorded previously,¹⁴ and the method has since been strongly recommended by Lawrence.¹⁵

A growing number of cases of diabetes are being reported in which the patients for no ascertainable reason are found to be resistant to insulin. In one such case doses as large as 1,600 units of insulin a day had no effect on the blood sugar. It is possible that these cases may be explained by an almost complete absence of the factor making for susceptibility. In contradistinction to these insulin-resistant diabetics, cases of spontaneous hypoglycaemia in which no hypertrophy or tumour of the islet cells can be found are continually being recorded. In such patients it is theoretically possible that the hypoglycaemia may be the outcome not of hyperinsulinism; but of the development of a state of a greatly heightened susceptibility to insulin secreted by the pancreas.

Finally, I would suggest the possibility of the existence of a type of diabetes due not to diminished secretion of insulin by the pancreas, but to a greater or less impairment of the organism's susceptibility to insulin. In such a case, although the output of endogenous insulin may be normal in quantity, the diminution or absence of the factor which is concerned in rendering the patient susceptible to insulin would produce a result identical with that of impaired production of insulin—namely, the clinical picture of diabetes mellitus.

I should like to thank Dr. J. W. Trevan of the Wellcome Physiological Research Laboratories for supplying me with the solution of crystalline insulin and Miss E. M. Marshall for controlling the diets of the experimental subjects.

A CASE OF AGRANULOCYTIC ANGINA

BY

A. DALY BRISCOE, M.A., M.B., B.CHIR.

Only five cases (all in females and four fatal) of agranulocytic angina have been reported in this country. In America and on the Continent, however, many cases have been investigated, and much has been written on the subject. By far the majority of patients have been females, and the mortality has been very high. Batten¹ was the first to record a case in England, and subsequent cases have been reported by Garrod and Williams,² Pilkington,³ Leys,⁴ and Abrahams.⁵ It appeared, therefore, that a case occurring in a man of 71, with subsequent recovery, was sufficiently unusual to be worth putting on record.

History of Case

The patient, a small, spare man, aged 71 years, had not felt well since June, 1933. He complained of feeling easily tired, of being irritable, and of having a poor appetite. The only previous history of any importance was an attack of renal colic six years before, which was followed by the passage per urethram of a small calculus.

He was first seen on August 31st, 1933. In addition to the symptoms mentioned above he had some difficulty and pain in swallowing, owing to an ulcer which was situated on the left side of his tongue in its posterior third. This was oval in shape and covered with a whitish slough. Its edge was not hard or indurated. There were no enlarged glands to be felt. All his teeth had been extracted some years before, and he was a non-smoker. He stated that his tongue had been sore for a few days. He continued at work for two days, but felt progressively poorly, and took to his bed on September 3rd, 1933. He was seen on the next day, when he had developed painful haemorrhoids, of which he had had previous attacks, and complained of pain on passing urine.

Digital examination of the rectum, which proved very painful, revealed a large, tender prostate. The urine was markedly acid, but no albumin or sugar was found; there was no deposit. The ulcer on the tongue was more painful, and there was considerable dysphagia, but the appearance of the ulcer was little altered. There was, however, some oedematous swelling around it, but not to any great extent. The painful micturition increased in intensity during the next two days, and the pain on defaecation was also aggravated. These symptoms now became the prominent features of the case, and proved more troublesome to the patient than the condition of his mouth.

On September 6th the temperature rose to 101.4° F. at 9 p.m., having been normal that morning. On September 8th there was some aphthous ulceration of the upper lip, and he was obviously feeling weaker, but his chief discomfort was that of frequent and painful micturition, and the haemorrhoids were still swollen and inflamed. The ulcer on the tongue did not appear to be any larger, but the slough appeared more "dirty." There was a slight icteric tinge of the sclerotics, but no enlargement of the liver was felt. The spleen was not palpable. There was no evidence clinically of any anaemia. The blood pressure was 116/70.

By September 10th the patient was much weaker, and with the continued fever it was felt there might be some obscure sepsis somewhere. A leucocyte count was done, but instead of a suspected leucocytosis a very marked leucopenia was found—370 per c.mm. It then became apparent that this might be a case of agranulocytic angina, and a blood film examined on the following day showed only 4 per cent. of polymorphs present, and the provisional diagnosis was confirmed. (The blood urea was 21 mg. per 100 c.cm.: this was done in view of the previous history of renal calculus.) Micturition continued to be painful, but no ulceration at the urethral meatus was discoverable, nor was there any anal ulceration, but the possibility of rectal ulceration could not be excluded. Insomnia was troublesome. At no time was the pulse raised above 100; more often it was 84 to 88, even when the temperature was in the region of 101°. The highest temperature recorded was 101.4°.

Blood Counts

The full pathological report on the blood film of September 11th was as follows: "The red cells appear normal, and there are platelets present. There are no abnormal white cells, but a differential count gives the following result, which shows a very marked polymorphonuclear leucopenia: polymorphonuclears, 4 per cent.; lymphocytes, 86 per cent.; monocytes, 10 per cent." A swab was taken of the ulcer, and on culture gave a moderate growth of haemolytic *Streptococcus longus*, with an occasional colony of *Staphylococcus albus*. On September 12th the tongue ulcer was definitely clearer, and the patient was certainly no worse.

On the next day a small quantity of dirty-looking material was discharged from the left nostril, and the patient then said that for two days his left nostril had been uncomfortable and slightly tender. On this date further blood films were examined, and the report was: "Red cells normal in size, shape, and colour; white cells similarly normal. A differential count, however, shows the condition to be very much the same as before: polymorphs, 5 per cent.; lymphocytes, 87 per cent.; monocytes, 8 per cent." From now onwards his condition slowly but steadily improved. The tongue showed signs of definite improvement each day. On September 14th the temperature was below 99° for the first time since September 6th.

On September 15th the differential count was: polymorphs, 17 per cent.; lymphocytes, 74 per cent.; mononuclears, 9 per cent.; no basophils or eosinophils. The next day the total white cell count was 1,800 per c.mm. The patient was now much better. The painful micturition was easier, and the haemorrhoids were subsiding. The tongue ulcer had cast its slough completely, leaving a clean base. From now on his progress was uninterrupted. The tongue ulcer healed rapidly. The slight superficial ulceration of the upper lip was quite healed by September 18th. A differential count three days later showed: polymorphs, 54.5 per cent.; lymphocytes, 33 per cent.; mononuclears, 7 per cent.; basophils, 0.5 per cent.; eosinophils, nil. He had now no complaints at all, and looked much better. He was able to get up on September 30th.

The blood was finally examined on October 7th and the following complete report made: red cells, 6,200,000 per c.mm.; haemoglobin, 86 per cent.; mean diameter, 7.4 μ ; colour index, 0.6; white cells, 5,700 per c.mm.—polymorphs 64 per cent., lymphocytes 31 per cent., mononuclears 4 per cent., eosinophils 1 per cent. This confirmed haematologically his complete recovery clinically.

During the succeeding six months this patient has kept well, and on April 6th, 1934, the following report on a blood film was received: "The red cells are of good colour, shape, and size. White cells are not seriously diminished. Differential count: polymorphs, 66.6 per cent.; lymphocytes, 28 per cent.; mononuclears, 4 per cent.; eosinophils, 1.2 per cent.; basophils, 0.2 per cent." There were no sequelae.

Comment

No specific therapy was employed. Blood transfusion was considered, but owing to its doubtful value was not carried out. Treatment by x rays has not been universally successful, and was not used, nor were injections of pentose nucleotide 96 or of sodium nucleinate given. There was never any ulceration of the pharynx or fauces. The ulcer on the tongue did not spread. The ulceration of the upper lip was quite superficial. There was evidently some ulceration of the nasal mucous membrane, and, although not certain, ulceration of the rectum and urethra was probable.

The points of special interest in the case are: (1) the fairly long prodromal period of slight ill-health; (2) that the patient was a male; (3) that his age was 71; (4) that the total leucocyte count fell to 370 per c.mm.; (5) that recovery was complete; (6) the high percentage of monocytes, which, according to Conner *et al.*,⁶ indicates a more favourable prognosis; (7) that the fever lasted seven days, which is the most usual time, according to Jackson *et al.*⁷

Conclusion

There was no apparent cause, and this case must be considered as primary or idiopathic agranulocytic angina.

It would appear that in any case of ulceration of the mouth, tongue, fauces, or any other mucous membrane without definite cause, yet with severe constitutional disturbance, an examination of the blood should be carried out to exclude the possibility of agranulocytic angina.

My thanks are due to Dr. W. F. Addey of Ipswich for his help in consultation; to Dr. E. Biddle, pathologist to the East Suffolk and Ipswich Hospital, for carrying out the pathological investigations; to my partner, Dr. E. F. K. Alford, for his assistance at various times; and to Mr. T. J. Shields, Librarian of the British Medical Association, for his help in looking up the references.

FULL-TERM EXTRAUTERINE PREGNANCY WITH LIVING CHILD

BY

W. ARKLEY STEEL, M.D. ST.AND., M.R.C.P.LOND.

HILLINGDON COUNTY HOSPITAL, UXBRIDGE

The recent publication of a very interesting article with a case report of full-term ectopic gestation¹ prompts the record of a similar case which occurred in the practice of Redhill County Hospital. This simulated a normal pregnancy so closely that at no time was the possibility of an ectopic gestation considered, although in the light of later knowledge the latter diagnosis should have suggested itself at the time of the patient's first attendance at hospital. The patient attended on several occasions over a period of four months.

Clinical History of Case

M. C., primipara, aged 24 years, was admitted to Redhill County Hospital, Edgware, on April 5th, 1932. At the age of 14 years she was operated upon for appendicitis, and was afterwards troubled with a ventral hernia, which developed in the operation scar. Each menstrual period was preceded by pain and a slight vaginal discharge. Her last menstrual period commenced on October 23rd, 1932.

Three weeks prior to her admission to hospital she had an attack of severe pain in the abdomen. She was impressed by the suddenness of the onset of the pain, which, she stated, occurred in the lower part of the abdomen, being much more severe on the right than on the left side. This severe pain, which lasted for about a day and then gradually diminished in intensity, was associated with a slight pain in both shoulders; she herself described it as "sharp" and "like twisting knives." Following this attack there had been a vaginal discharge, which after a fortnight diminished in amount.

When admitted to hospital she described the pain as being much less severe and of a dragging nature, but added that the act of micturition was accompanied by pain. She was extremely nervous and apprehensive of examination. The temperature was 98° F., pulse 86, respirations 24. The bowels were regular. A centrally situated tumour reaching to the umbilicus was regarded as the uterus enlarged to the period of cystitis. Tenderness was present over the whole abdomen, but was most marked in the iliac fossae. The presence of this tumour was confirmed by vaginal examination. The cervix was soft and the external os closed. There was tenderness in

the right and left fornices. The fundus of the uterus could not be defined from the tumour, which filled the pelvis and reached into the abdomen. A catheter specimen of the urine showed no abnormality. She was discharged from hospital on April 14th, 1932, having been then for some days entirely free from symptoms.

The patient reported at the ante-natal clinic on May 9th, 1932, and thereafter attended on three occasions prior to her readmission to hospital on July 29th, 1932. A radiogram taken on July 16th showed the foetus had assumed the transverse position. The head was lying in the left iliac fossa. Attempts at external version failed to alter this, and the position was maintained until August 9th, when it was decided to attempt external version under anaesthesia.

In contrast to the difficulty experienced in previous attempts at version, the head was very readily moved and maintained in the vertex position. As the head commenced to turn it was noted that a definite "snap" was conveyed to the palpating hand. The head was floating well above the brim of the pelvis. A vaginal examination was carried out, and a large placenta was felt occupying the entire pelvis. It was seen at once that the patient's condition had become worse, and the anaesthetic was immediately discontinued. She became very blanched and extremely shocked. When conscious she complained of severe abdominal pain. It was thought that the uterus had been ruptured, and an operation was immediately carried out under chloroform and ether anaesthesia.

Operation

The abdomen was opened by a midline incision. The abdominal cavity was found to be full of blood. A living female child was extracted. The umbilical cord was cut between ligatures. A normal uterus was then palpated and seen lying anterior to the placenta, which swayed at the end of a strap-like pedicle. This pedicle was from 3 to 4 inches broad, and was attached to the posterior aspect of the right broad ligament. As large blood vessels were seen coursing through the pedicle, it was accordingly severed between clamps and the stump ligatured with catgut. A thick-walled, ruptured sac was adherent to the coils of the small bowel and also to the omentum. The sac was readily separated, and very little of it had to be left behind owing to its persistent adhesion. The patient's condition was extremely precarious. A pint of the blood which had been sucked out of the peritoneal cavity during the course of the operation was given to her intravenously. Thereafter her condition rapidly improved, and undoubtedly this case marks a further illustration of the life-saving value of auto-transfusion of blood. The convalescence was uneventful, and she was discharged on September 7th, 1933. She was examined again on May 7th, 1934—that is, twenty months after her operation, when she stated that menstruation was in every way normal. At no time since the operation had she experienced any pain or discomfort.

After the operation the child showed signs of shock but rallied with treatment. Her colour was then good, and she seemed apparently healthy. Unfortunately the child died suddenly twelve hours after birth.

Post-mortem Findings

A necropsy was carried out on the body of the child, and the following details were noted:

Length of child	...	17½ inches
Weight of child	...	6 lb. 11 oz.

Although a careful examination was made, no abnormality or deformity was found. Sections of different parts of the skeleton were reported on as follows:

"The sternum shows centres of ossification in the manubrium and three centres in the body. Ossification is commencing in the lower end of the femur in the lower epiphysis. The epiphysis at the upper end of the tibia shows no sign of ossification. The placenta weighs 3 lb., is fully formed, and measures 8 inches in diameter. It appears to be perfectly normal, except for the thickness of the membranes attached to it."

Commentary

The tarsal bones were also sent for examination, but unfortunately no report of these was obtained.

There seems to be little doubt from the details given above that this was a full-time child. It would appear that the "snap" which was noticed at the commencement of the version was due to the rupture of the sac, and this case must be the more remarkable from the fact that the child survived the interval of at least one hour which elapsed between the version and the time of operation.

Clinical Memoranda

SPONTANEOUS RUPTURE OF THE UTERUS AT THE TWENTY-FOURTH WEEK OF PREGNANCY

Uterine rupture at any stage of pregnancy is becoming less frequent. This is to be accounted for by the greater knowledge of, and better attention paid to, the conditions which predispose to it, to the better prenatal care of patients, and to the more careful and gentle treatment of labour, especially when complicated.

A woman, aged 28, was admitted to Addenbrooke's Hospital as an emergency on June 18th, 1930. She had had two healthy children after normal pregnancies and confinements. Since the previous December she had had amenorrhoea, and was about twenty-four weeks pregnant. Up till and during the previous day she had been perfectly well, and had had a normal night's rest. At 6 a.m. she was up and moving about her house, starting her daily duties, when she suddenly had very acute abdominal pain and faintness. Her doctor was sent for, and when he arrived he found her in a state of collapse. He very rightly diagnosed some form of internal haemorrhage, probably intrauterine and of the concealed accidental type. It is important to note that there was no history of the slightest trauma, fall, or shock.

The patient was immediately sent into hospital, and I saw her shortly after her arrival. She was exceedingly pale, the pulse was uncountable (about 180 to 200), and she was only semi-conscious. In fact, her state was one of very profound collapse. On examination the abdomen was not particularly tender, and, when roused, she did not complain then of much pain. Foetal parts could be felt in the lower abdomen in a swelling corresponding in size with the period of amenorrhoea. A diagnosis of intrauterine haemorrhage was made, and the vagina was plugged pending some reaction on the part of the patient. She was infused both intravenously and subcutaneously, and kept under morphine. In the evening the pulse was 120 and fairly satisfactory. The patient was by this time quite conscious, but no uterine pains had developed. The abdomen had become more generally distended, and was tender all over. In addition, a mass about the size of a small coco-nut could be felt low down in the abdomen and rising out of the pelvis.

The diagnosis was still uncertain, except that it was now obvious that the internal haemorrhage, whatever the origin, was intraperitoneal. It was decided, therefore, to open the abdomen. Under nitrous oxide and oxygen the abdominal wall was thoroughly infiltrated with novocain. On opening the peritoneum the first things that presented were foetal membranes over foetal parts; the peritoneal cavity contained much dark blood and clot. On further investigation the ovum was found intact, the placenta seemingly being attached to the back of the uterus, which, before the abdomen was opened, had been felt as the mass low down and rising from the pelvis. A touch with the fingers at the back of the uterus completely separated the ovum containing its six-months foetus, and the whole was lifted out. On inspecting the back of the uterus a pouting laceration, about two inches

long, with irregular margins, was seen. Having removed as much blood as possible, a rapid supravaginal amputation of the uterus was performed, as being the best means of dealing with so desperate a condition. Saline in quantity was left in the abdomen, and the wound rapidly closed. For the next four days the patient seemed to be getting on well, and every hope was entertained of her recovery. Quite suddenly, however, in the afternoon of the fifth day, she took a turn for the worse and died. Necropsy was refused.

The upper part of the uterus removed at operation shows the rent in the centre of the back of the fundus. The specimen was sent up to the medical schools, and very careful microscopic examinations were made in the department of pathology. The following is the report.

"Sections have been made from the unaffected and affected portions of the uterus. In the unaffected portion there is normal uterine muscle, with perhaps, in places, a tendency to a very slight increase of fibrous tissue. In the affected portion the site of rupture shows a large collection of polymorphonuclear leucocytes, which may be an indication of infection or an expression of general leucocytosis of a post-haemorrhagic type. The muscle is degenerate and hyaline at the site of rupture, and is invaded by collections of large mononuclear cells and, here and there, giant cells of the foreign body type. These are not suggestive of any specific inflammation, but merely of a reaction of chronic type. Special staining for fatty degeneration gives negative results. A Gram stain for organisms shows numerous large Gram-positive spherical bodies, which were at first thought to be members of the yeast group. Further and more detailed study, however, disposes of this. They are probably aberrant collections of pigment, some of which are being digested by the polymorphonuclear leucocytes. The cause of the chronic infection of the uterine muscle must remain uncertain. An atypical syphilitic infection is an outside possibility, but this is mainly speculative."

Uterine rupture is roughly divided into two kinds: (1) complete, when the peritoneum is involved; (2) incomplete, when the tear enters the parametrium, having usually extended up from the cervix. Complete rupture, of which this case is an instance, can occur spontaneously, quite apart from powerful uterine contraction or operative delivery. Such would occur in a uterine wall weakened by myomectomy or Caesarean section, when the resulting scar tissue causes a weak spot in the wall. It can occur in a uterus congenitally weaker than the normal, such as the so-called "infantile type," or in a uterus bicornis. But if spontaneous rupture does occur it almost always does so at or near term. In this case spontaneous rupture occurred at the twenty-fourth week without trauma or uterine contraction, and there had been no operative intervention in the uterine wall previously. Some morbid change in the uterine muscle must have occurred locally, and the fact that the patient had had two previous normal pregnancies and labours shows that the change must have taken place since the last puerperium. The microscope has shown these changes in the wall. It was unfortunate that the ovum was destroyed after it had been carefully kept by me with the uterus from which it had come. An examination of the foetus might have thrown some light on this rather obscure condition. The refusal of necropsy also possibly robbed us of important information.

In conclusion, it should be mentioned that no drugs had been taken or administered, and the fact that the ovum escaped from the uterus intact disposes of any suspicion of an attempt having been made to procure abortion. Diagnosis was made difficult by the absence of trauma and the early stage of gestation at which rupture took place.

I am greatly indebted to Dr. R. A. Webb of the department of pathology for the trouble he has gone to in trying to elucidate the case for me.

J. R. CAMPBELL CANNEY, M.A., M.D., B.C.E.
Cambridge.

SPONTANEOUS RECOVERY IN SUPERIOR
MESENTERIC THROMBOSIS

An interesting case of acute abdominal disease was recently admitted to the Kimberley Hospital, and with a view to obtaining the comments and opinions of others I should like to recount its salient features.

A male, aged 74, complained of intense abdominal pain of sudden onset and of about four hours' duration; there was no history of similar attacks or of any symptoms pointing to abdominal disease. The patient gave a history of a long-standing morphine habit, and stated that just prior to the onset of the pain he had taken half a drachm of liq. morph. hydrochlor. Vomiting occurred once at the onset. Up to the time of the attack the bowels had acted regularly and micturition had been normal.

The pain was localized to the upper abdomen, and was most severe at a point just above and to the left of the umbilicus. The abdomen was extremely tender and slightly rigid on palpation over this area, but beyond this inspection, palpation, and auscultation revealed nothing abnormal. Both pupils were constricted, and reacted to light and accommodation. Both knee-jerks were present, the plantar response bilaterally flexor. No abnormal constituents were found in the urine. Shortly after admission a stool slightly suggestive of melaena was passed, and in view of this a tentative diagnosis of partial intestinal obstruction was made and a laparotomy performed.

At operation a loop of ileum, some four feet in length, was found to be dilated: the walls were congested, friable, and of a dark plum colour, and bled very easily on handling. The related mesentery was much thickened and in places gangrenous, while the blood vessels were felt in it as thickened cords. These vessels were traced up to the root of the mesentery, and in no part of their course could pulsation be detected. It was concluded that the condition was one of superior mesenteric thrombosis, and, in view of the patient's age, his poor general condition, and the length of gut involved no attempt at resection was made; the abdomen was closed with as little handling of its contents as possible.

The patient was placed on glucose and brandy, and morphine was given freely. For three days clear bile-stained fluid was repeatedly vomited, and for a further three days the patient hiccupped continuously. During this period the bowels were relieved with enemata; the stools were always slightly suggestive of melaena. A week after the operation, with dramatic suddenness, the pain, vomiting, and hiccupping ceased, and normal stools were passed. At the present time (a fortnight after operation) the patient is almost completely recovered, is on a steadily increasing diet, and daily exhibits an improvement in his condition.

The prognosis for superior mesenteric thrombosis, as given in the standard works on surgery, is gloomy in the extreme, yet here we seem to have encountered an undoubted example of this condition which has exhibited a spontaneous cure. I shall be glad to learn if any other case of superior mesenteric thrombosis has shown a spontaneous recovery of this nature, and also to receive any suggestions for an alternative diagnosis which will fit in with the observed facts. It has been suggested to me that the case may have been one of volvulus, which was "undone" spontaneously either immediately before the operation or during the induction of anaesthesia. The short history, the slight vomiting, the absence of symptoms of a complete strangulation of the gut, the thrombotic nature of the vessels (with absence of pulsation) in the gangrenous mesentery, and the slight possibility of a volvulus which could affect the gut to such a severe extent untwisting itself, make me disinclined to accept this diagnosis.

This patient was admitted to hospital under the care of one of the honorary surgeons, Dr. A. E. Hill, who has kindly given me permission to offer this case for comment.

Kimberley Hospital.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

DERBYSHIRE BRANCH

DISEASES AND INJURIES OF THE LOWER SPINE

In his presidential address to the Derbyshire Branch of the British Medical Association at Matlock, on June 20th, Dr. C. W. BUCKLEY of Buxton discussed diseases and injuries of the lower spine, with special reference to compensation cases.

Dr. Buckley stressed the importance of accurate diagnosis in cases of pain and stiffness in the back, which were common in industrial practice and in compensation claims after injury sustained in the course of employment. Such claims would be fought by the insurance company, and the opinion of the patient's medical practitioner would be contested by the evidence of expert witnesses called by the company, and relying often on a single examination. The judge was generally sympathetic, provided that the medical practitioner restricted himself to witnessing to facts. It was well to remember the American dictum that exaggeration was as common as malingering was rare, being the natural defensive mechanism of one who feared that he presented inadequate external evidence of the pain he felt. An x-ray examination was essential if litigation was in prospect; it would reveal such grosser conditions as fractures and abnormalities, and a report by a radiographer should be obtained. This must be considered with the clinical findings.

SACRO-ILIAC AND LUMBO-SACRAL STRAIN

Dr. Buckley reviewed the anatomical factors in detail, commenting on the commoner abnormalities. Sacralization of the fifth lumbar vertebra tended to throw an abnormal strain on the ligaments, and predisposed to sacro-iliac strain. The position of the fifth lumbar nerve root rendered it especially liable to be affected by such strain, and it was desirable to investigate carefully the distribution of pain in the lower extremity in cases of strain, and, by means of Head's diagrams, to determine as far as possible the nerve roots affected. History-taking was of the first importance, and the exact nature of the employment should be noted. Not all miners worked at the coal face, and in the case of motor-driving there might be strain from a badly tilted seat or too long a reach to the driving controls. Lumbo-sacral strain was more common in heavily built men, and sacro-iliac strain in the slender type with poor muscles and posture. Occupational factors bulked largely in the production of lumbo-sacral strain, and trauma was more frequently the cause in the sacro-iliac variety. In the physical examination abnormalities should be noted, including any sign of muscle spasm or flat-foot. The degree of inability to touch the toes while standing should be compared with that when sitting. In sacro-iliac strain the former was prevented by hamstring spasm, but was easier in the sitting posture. In lumbo-sacral strain sitting did not help, and the degree of movement might be greater when standing. This test should always be made, and simultaneously the existence of any spasm of the hamstrings or lumbar muscles be detected. The lateral and rotation spinal movements should be tested next, and then the raising of the legs in the recumbent position, first with the knees flexed and then with them straight. In sacro-iliac strain straight leg raising was checked, as a rule, at about 140 degrees by spasm of the hamstring muscles, which rotated the ilium on the sacrum. The unilateral pain thus induced was almost diagnostic if in the region of the joint. If, however, the pain was felt in the middle of the thigh it was likely to be due to perineuritis of the sciatic trunk. With the patient lying face downwards hyperextension of the thighs was almost always painful in low back cases. In sacro-iliac strain the point of maximum tenderness was just internal to the posterior spine of the ilium; in lumbo-sacral strain it was over the lower lumbar spinous or transverse processes. Irritation of the sensory nerves in the articular ligaments might give

rise to more disability than fracture of minor bony structures. Sacro-iliac strain and subluxation commonly resulted from violent muscular effort, with or without the presence of developmental anomalies, and especially when the muscles were fatigued by prolonged effort, and failed to support the ligaments. They also might be due to blows to the lower part of the back in the stooping position. Other causes were long standing and stooping or lying in fixed and faulty positions; repeated slight strain of this kind set up chronic fibrositis and chronic relaxation of the joint. Lumbo-sacral strain might be static or traumatic, in the latter case being often associated with sacro-iliac strain. Stretching of the posterior ligaments due to weight-lifting might cause sudden pain shooting down the sciatic nerve. The extreme of lumbo-sacral strain was spondylolisthesis, the sliding forward of the fifth lumbar vertebra over the upper surface of the sacrum. It could only occur if the articular processes were in the sagittal plane, or had been fractured. In one case of back pain there had been well-marked, long-standing scoliosis, nuclear prolapse of several disks, and lipping of some of the vertebral bodies, but the cause was actually lumbo-sacral strain due to the plane between the mobile lumbar spine and the relatively immobile sacrum being little removed from the vertical, thus throwing great strain on the ligaments. Nuclear prolapse was of great importance, leading to penetration of the vertebral body and rendering it more prone to further injury. Claims for compensation which were supported by radiographical evidence were rarely contested, but some strains, which resulted in really serious disability, would not be admitted as genuine unless sound clinical proofs were forthcoming.

RADIOGRAPHIC EVIDENCE

Dr. Buckley said that careful examination on the lines he had indicated would generally serve to detect malingering and to demonstrate how far exaggeration was a factor. Radiographical examination was essential in all cases of injury to the back and in all cases of persistent pain in the absence of trauma. Lateral as well as antero-posterior views should be taken, and would reveal fractures of vertebral bodies and transverse and spinal processes, displacements of vertebrae, disalignment of the pubis, sacralization and spondylolisthesis, osteitis deformans, arthritis, neoplasms, and tuberculous and rarer conditions. A compression fracture of a lumbar body might thus be discovered which had occurred some years before the onset of symptoms. Kummell's disease, a slowly collapsing fracture of a vertebral body, only gave rise to symptoms when the patient had started work again after treatment for a bruised back. Secondary deposits in the lumbar spine and pelvic bones might be the first evidence of a primary growth in the prostate. Arthritis of the spine or spondylitis deformans might appear as ankylosing spondylitis in young adults in the lumbar region, but sometimes higher. Stiffness in the back progressed rapidly to complete ankylosis. In about 80 per cent. ankylosis of the sacro-iliac joints began early, and might be the first demonstrable radiographic sign. The spinal column ultimately became a rigid bar—straight if the patient had been kept at rest, but otherwise with varying degrees of kyphosis. Osteoarthritis of the spine was comparable to this condition in other joints. Slight lipping of the vertebral bodies was, however, of no importance, and might be regarded as one of the accompaniments of advancing years. Small osteophytes in the lumbar spine were also commonly seen, and might become very large without giving rise to symptoms. They might, nevertheless, be an important contributory factor in disablement from minor accidents. The largest osteophytes in the lumbar spine appeared on the left side if the man was right-handed, and on the right in the left-handed, indicating the part played in their causation by spinal movement and strain. In such back cases, without severe strain but with osteoarthritis present, the man could be passed for light work. It was most important that osteoarthritic patients should realize that they were not suffering from true rheumatoid arthritis, which always suggested to them progressive crippling. Continued activity within the limits of their ability was most desirable.

Reviews

PRINCIPLES OF GYNAECOLOGY

The fourth edition of Professor BLAIR-BELL's *Principles of Gynaecology*¹ comes with all the attractions of a new work owing to extensive revision and the long interval since its previous issue. A historical introduction, based on brief sketches of the lives of the chief figures in gynaecology's roll of honour, and a section on ethical and medico-legal problems have been added. Both are welcome. We are in full agreement with the author's remark in the preface that "the imprint of personality is a valuable asset to any textbook," and would add that there can be no question of his success in this regard. The outstanding characteristic of this book is the extent to which the author's attitude of mind and outlook are revealed, as if by an autobiography. He breaks away from traditional views and methods in a manner that stimulates thought and should make his book of value and interest to all engaged in the practice and teaching of gynaecology and to those preparing for the higher examinations in the subject.

From its first appearance this book influenced the change in the arrangement of gynaecological works from an anatomical to a pathological basis, and its general lay-out calls for no comment. The interposition of Part II on case-taking and examination of the patient between Part I on structure and Part III on function does, however, arouse curiosity as to the reasons therefor. The next two parts cover derangements, first of structure then of function. All the foregoing are written with the object of giving the student a broad biological view, and as a rule very successfully. Here and there, however, broad principles are lost in detail. Thus the meaning and implications of the reduction of chromosomes during maturation are lost in describing the manner of their reduction. Neither among the possible causes of abortion nor under "selective sterility" is there any reference to lethal gametic combinations, well recognized as cause of loss of zygotes in breeding experiments. Part VII, on infections, gives a sound and judicial view of their aetiology, prophylaxis, and treatment. The introduction of Part IX, on neoplasms, is possibly the most thought-stimulating portion of an account of the pathology and clinical features of new growths. The relative value of treatment by radium and surgical operation in uterine cancer, the selection of cases of ovarian cyst for removal by the abdominal or vaginal route, are considered in the same open-minded spirit as was the choice of time and method of operation for pelvic infections. Lead therapy for cancer receives fuller attention than would be expected from one who had not, as the author has, initiated and developed it. Operative procedures are clearly described and well illustrated.

This edition will undoubtedly add to the influence its predecessors have had on thought and practice in gynaecology. There is no question of its interest and value to those who have some basis of experience in the subject, but there may be some reservation regarding its appeal to the average unqualified student, owing to its highly individualistic character. His predilections and idiosyncrasies have led Professor Blair-Bell to use a terminology of his own devising, and a new series of uterine "ponations," added to the inevitable versions and flexions, is a source of further confusion. The beginner's

¹ *The Principles of Gynaecology: A Textbook for Students and Practitioners.* By William Blair-Bell, B.S., M.D., F.R.C.S., F.C.O.G. Fourth edition, revised and largely rewritten with the assistance of M. M. Darnow, M.D., B.Ch., F.R.C.S.E., M.C.O.G., and Arthur C. H. Bell, M.B., B.S., F.R.C.S., M.C.O.G. London: Baillière, Tindall and Cox, 1934. (Pp. xiv + 548; 507 figures, 16 coloured plates. 55s., postage 9d.)

sense of proportion may be distorted by the undue attention given to subjects that attract the author, such as hermaphroditism and others among the congenital atavisms and malformations. But even should the student fear direct study of the book, he is bound to benefit indirectly by the stimulus it will give his teachers; and, should he advance further into the subject, it will then have an irresistible appeal.

PHYSICAL MEDICINE

A Clinical Textbook on Physiotherapy for physicians and medical students² has been produced by Dr. Grober of Jena, with the assistance of six German and Austrian colleagues. Three chapters, on massage, pneumotherapy, and climates, with an introduction, are supplied by Dr. Grober, who is director of the Physico-Therapeutic Institute at the University of Jena. Each section deals with the physical and physiological aspects, the technique, and the indications of the special methods under consideration. It is claimed in the introduction that physical medicine is the oldest, and should be one of the chief branches, of medical study and practice. It is now based on scientific physics, not on any vague belief in the general healing power of Nature. No progress can be made in this branch of medicine without precise physical and physiological data. Dr. Grober defines the scope of physical medicine so as to include the whole range of the electro-magnetic energy spectrum, from electric rays, through infra-red, visible rays, ultra-violet rays, x rays, and radium to cosmic rays. This gives a corresponding range of physical methods—electro-, thermo-, photo-, x-ray, and radium applications—to which must be added at the beginning mechanical energy, in the form of massage and of general and respiratory remedial exercises, and at the end the all-inclusive influences of climate.

Large claims are made for physical medicine as rightly forming part of the training and practice of every physician, and not only a specialty. This will, if realized, prevent resort to quacks, but should also prove an effective means of bringing the practitioner into close contact with the patient and of observing his individual reactions. Physical medicine can thus serve a diagnostic end of wide general application. On the principle of not giving a *Amati* violin to a carpenter to mend, Dr. Grober considers that physical treatment ought to be administered by the medical man—but the attendant must be trained and experienced, working under close medical supervision. The large amount of elaborate apparatus here described certainly places many procedures outside the scope of the general practitioner. In every chapter the simplest methods of using the various forms of energy, including self-treatments by patients, are described, the more elaborate forms being regarded as an extension into a specialty, according to the familiar process in the relations between general and special practice.

Spa treatment is not discussed, and the chapter on hydrotherapy, by Professor Strasser, includes an up-to-date physiological section, the recent work of Hauffe on action at a distance being also critically considered. Hydrotherapy is here regarded broadly as a form of thermotherapy plus the mechanical action of water at rest and in motion. The indications cover the whole field of chronic disease, but very little space is devoted to the disorders of locomotion: indeed, chronic rheumatoid arthritis and osteo-arthritis are only casually mentioned, and rheumatic disorders are treated somewhat cavalierly throughout the book, being accorded merely three lines in the index, and then only under the general heading of

"Joint Disorders." The chapter on kinesotherapy includes both free movements and those with apparatus of many kinds, simple and complicated, and also the manipulation of joints, this chapter being divided into sections according to the kind of tissue acted upon. In his chapter on climate the editor deals with the usual three special climates—desert, seaside, and alpine—and also with gradations of inland climates, especially forest. Civilized man, he says, lives habitually in an artificial "room climate," produced by heated houses and clothing, so that any kind of exposure to open air is a climatic stimulus. He holds that climatic treatment requires long periods, a two to three weeks' holiday being quite inadequate to produce any but a temporary stimulus. Altogether Dr. Grober's work is a useful contribution to the serious study of modern physical medicine.

BACTERIAL CLASSIFICATION

In a recent monograph devoted to the question of bacterial types in microbiology Dr. MAX GUNDEL has assembled and reviewed critically all the available knowledge bearing on this subject.³ Increasing information on the pathogenic bacteria has hardly tended to simplify matters, for the bacteriologist of to-day has not merely to concern himself with bacterial species, but also with the many quite definite types into which many species may be divisible. One need look no further than the pneumococcus and the dysentery bacillus for examples of this. And this subdivision into types is not merely a matter of scientific interest; in many cases it is of the highest importance from the point of view of epidemiology and clinical medicine. Dr. Gundel speaks with authority on the subject, for he has devoted much time to a study of this aspect of bacteriology, more particularly as it applies to the pneumococcus and streptococcus, and his monograph is one of value. Of course the information is available to those who care to consult original papers and modern textbooks like the *System of Bacteriology*, but it is an advantage to have it all collected together, and for those who desire this, and read German, Dr. Gundel's monograph should prove eminently satisfactory.

REALITY AND CONDUCT

Morality and Reality,⁴ by Dr. E. GRAHAM HOWE, is a useful but curious book. It sets forth a considered and consistent philosophy: it does more than this—it offers, as every philosophy should, a stimulus and a guide to conduct. Fundamentally it is wise; occasionally, in some of its diagrams, analogies, and applications, it seems to verge on the fantastic. The subtitle of the book declares it to be "an essay on the law of life," and this, indeed, it is, as the author sees the matter and as he assuredly will induce or help others to see it. He drives his main point home repeatedly and effectively, though all his reinforcements have not an equal value or validity. To discourse on the right, the good, and the true, with such interest and force and ingenuity is not a common gift; indeed, as the author says,

It has always been cheap but fashionable to gibe against the person who asks "What is Truth?" But the fact remains that the answer is never an easy one because the truth is living and moving; it is only relative and it is always hidden under some transient mask of material form.

It is impossible to summarize the argument and the successive lines of thought extending through the volume,

² *Die Typenlehre in der Mikrobiologie*. Von Professor Dr. med. et phil. Max Gundel. Jena. G. Fischer. 1934. (Pp. 192. R.M.8; geb. R.M.9.)

⁴ *Morality and Reality. An Essay on the Law of Life*. By E. Graham Howe, M.B., B.S., D.P.M. London: Gerald Howe Ltd. 1934. (Pp. 126. 6s. net.)

² *Physikalische Therapie. Klinisches Lehrbuch*. Edited by Professor J. Grober. Jena: Gustav Fischer. 1934. (Pp. 364; 172 figures. R.M.16; geb., R.M.18.)

and very difficult to indicate fairly its thesis. The latter task may be attempted thus. Reality means "that which is now, which is not, as a whole, what I want." Morality is "a matter of form; it is behaviour about reality, an attitude towards life, a code or system of rights and wrongs." The relations between the two are antagonistic. "Morality of any kind has always been and must always be the enemy of life as well as science, for it seeks to impose an artificial restriction for its own convenience. . . . The discipline imposed by a morality seems to have for its purpose an escape from the restrictions of reality, the discipline of which it finds irksome and does not approve, substituting another more suitable to its own convenience." The true conduct of life, and of teaching, should be based upon the acceptance of reality (things as they are though they are not what I want them to be), and not upon fighting it, ignoring it, or running from it. At the same time acceptance is not inertia, but ordered, gradual, continuous growth. The general progress of the author's thought may be imperfectly indicated by the titles of his chapters: "The Good and the True," "Law and the Child," "Law and the Family," "Law and the Social Group," "The Fulfilment of the Law." In these chapters Dr. Howe writes not from the strictly ethical, academic, or philosophic point of view, but from that of a physician experienced especially in dealing with the difficulties of childhood by psychotherapeutic methods. These can never be fully successful unless, as here, they are founded on considered beliefs, clearly held and sincerely followed and applied.

EARLY FORERUNNERS OF MAN

The publication of the book with this title by a foremost authority on evolution is to be welcomed as presenting a new departure in the method of approach to the problem of the evolutionary origin of the primates.¹ Professor LE GROS CLARK combines in this work the qualities of an anatomist with those of a field naturalist and a not inconsiderable artist. The result (strange for a book of this kind) is that the book, whilst primarily meant as a contribution to an academic subject, will be found of great attraction and interest by non-anatomists. The zoological names for animals are of necessity complicated, but need not deter the general reader from a perusal of this volume, for from it he will obtain a rapid insight into the methods used in tracing the evolutionary origins not only of the primates but of any other order.

Many attempts have been made to build up a scheme of the phylogenesis of the primates by selection of a particular anatomical system (for example, the teeth or the brain), but the author of this volume has set himself the task of taking into account all the anatomical characters, and thus avoiding the danger of having the classification based on evidence obtained from one system contradicted by that of another system. This constitutes, so far as we know, the first attempt to put together all the relevant morphological and palaeontological evidence bearing on the problem. The evidence is presented clearly, and is illustrated richly, many of the excellent line drawings being from the author's own pen. It is put forward, as a result of the analysis of all the available information, that the primates originated from the earliest of the placental mammals, and that already in Cretaceous times they had become separated into a distinct order. The classification of the evolutionary radiations of the primates into Lemuroidea, Tarsiodea, and Anthropeidea is supported, but the author considers that these were already distinct at the very base of the primate branch.

¹ *Early Forerunners of Man. A Morphological Study of the Evolutionary Origin of the Primates.* By W. E. Le Gros Clark, D.Sc., F.R.C.S. London: Baillière, Tindall and Cox, 1934. (Pp. vi + 394; 89 figures. 15s; postage 9d, abroad 1s. 3d.)

Whilst a positive answer is given as to the inclusion of the lemurs in the primates, it is carefully shown that they became differentiated from the basal primate stock independently of other primates, and that it is therefore unjustifiable to postulate a "lemuroid" phase in the ancestry of the higher primates.

The ever-tantalizing question of the origin of man is treated in an entirely detached and scientific manner according to the evidence. It appears that the human phylum became differentiated from the anthropoid ape phylum at an earlier age than is generally conceded—namely, when the hypothetical common ancestor (a type deduced from the study of the dynamics of variation) was not much bigger than the modern gibbon. Still the author considers that the evidence supports the conception that man has arisen from an ancestral stock which can be legitimately termed an "anthropoid ape." The author's own studies of tarsioidea have led him to the conclusion that this sub-order was separated from the anthropoids at the very beginning of the Eocene period, and that many of the "anthropoid" features of the modern Tarsius are the result of parallel development. But the evidence does not oppose the view that the Tarsiodea and Anthropeidea had a common origin from the primate stock; indeed, it seems that the common ancestor of these two sub-orders would come within the definition of the Tarsioids (*Prototarsioids*). The controversy as to the position of the Tupaiodea (tree-shrews) in the evolutionary scale is considered in detail, and the conclusion reached that these animals cannot be put in the order of insectivores, but must be included in the primates. The recent discovery in Mongolia of a fossil tree-shrew—*Anagale*—is adduced as evidence of a closer approximation of the tree-shrews to the lemurs than is seen by a study of the modern representatives of the Tupaiodea. The morphological and palaeontological evidence indicates that there has been a great deal of parallel evolution among the primates since their first differentiation as a separate order, and the bearing of this in modern conceptions of evolution is discussed.

Professor Le Gros Clark is to be congratulated on a most scholarly production, which is a fitting prelude to his assumption of the duties of the chair of anatomy at Oxford.

Notes on Books

Forensic Medicine,² by Professor SYDNEY SMITH, is now so well known as to need no recommendation. The fourth edition has just been published, and the author has wisely refrained from increasing its size by more than the few pages necessary to make minor alterations and improvements to keep the volume up to date. It will continue to enjoy wide popularity amongst students and practitioners.

The large and handsome textbook of operative obstetrics³ by Professor BRIQUET of São Paulo, with nearly 400 illustrations, affords readers of the Portuguese tongue a full and well-arranged account of the important subject with which it deals. It is up to date, well furnished with references to the European literature, and provided with an adequate index. The volume does equal credit to its author and its printer.

The eleventh volume of the *Archives of Neurology and Psychiatry*,⁴ from the Central Pathological Laboratory of the London County Mental Hospitals, edited by Dr. F. L. Golla, who is director of the laboratory, consists of forty reprints of articles published elsewhere during the last three years. Perusal of this volume will show the high

² *Forensic Medicine. A Textbook for Students and Practitioners.* By Sydney Smith, M.D., F.R.C.P., D.P.H. Fourth edition. London: J. and A. Churchill Ltd. 1934. (Pp. 644; 179 figures. 25s.)

³ *Obstetrics Operative.* By Raul Briquet, São Paulo: Companhia Editora Nacional. (Pp. 541; 373 figures.)

⁴ No. 344. London: P. S. King and Son, Ltd. 1934. (15s.)

level of excellence attained by the workers in the London County Council's Central Pathological Laboratory at the Maudsley Hospital, with its enormous available wealth of clinical and pathological material.

In a pamphlet on the Treatment of Bronchial Asthma⁹ Dr. DÉROT gives a straightforward account of the most important methods employed in treating this common complaint, concluding, as so many of us have concluded, that no two cases are either identical or in need of the same treatment. The pamphlet may be recommended as containing a great deal of information and advice useful to the general practitioner of medicine.

*Dental Pharmacology and Therapeutics*¹⁰ has been written as an aid to the dental student or practitioner in solving some of his daily problems, and its author, Professor BLAYNEY, expressly states, not as a book for detailed reference. Nevertheless, by a happy combination of clinical experience and professorial knowledge, he has produced a work which may well serve both purposes in the daily work of the dentist. The notes on phenol and alcohol are good examples of this happy combination.

⁹ *Le Traitement de l'Asthme Bronchique*. Par Dr. Maurice Dérot. Paris: J. B. Ballière et Fils. 1933. (Pp. 44. 6 fr.)

New Preparations

TANNA-FLAVINE FOR BURNS

We have received from the British Drug Houses Ltd., Graham Street, City Road, N.1, a leaflet, which they have published recently, in reference to "tanna-flavine," a preparation of tannic acid with acriflavine for the treatment of burns and scalds. The manufacturers anticipate that industrial firms will include "tanna-flavine" as a part of their first-aid equipment; also that it will be used in hospitals, particularly in the casualty wards. It is issued in packages, the contents of each of which, when used in accordance with the directions, are sufficient for the preparation of 100 c.cm. ($\frac{3}{4}$ fluid ounces) of a solution containing 20 per cent. of tannic acid and 0.1 per cent. of acriflavine "B.D." The solution is painted over the raw surface with a sterilized brush, or applied with gauze soaked in the solution. Immediate coagulation takes place on the wound. The area is then dried, preferably by means of a current of hot air from an electric drier. A second application and subsequent drying may be undertaken immediately; indeed, this is often necessary when the surfaces have been cleansed with normal saline solution. The burned areas are exposed to the air from the beginning of the treatment until the coagulated layer has separated or has been removed; this usually takes from twelve to twenty-one days. During the treatment the bedclothes should be supported by a cage, and the patient kept warm.

SODIUM PENTOSE NUCLEOTIDES

"Pentide" is an 8 per cent. solution of sodium pentose nucleotides prepared by Allen and Hanburys Ltd. (London, E.2) for the treatment of agranulocytosis or malignant neutropenia, and other conditions in which increased production of polymorphonuclear leucocytes is desirable.

Two types of agranulocytosis—that is, absence or diminution in number of the granular (polymorphonuclear) leucocytes—are known: true agranulocytic angina, of unknown aetiology; and malignant neutropenia, secondary to an obvious acute infection. True agranulocytic angina, characterized by ulcerative lesions in the mouth or pharynx, is usually acute and fatal. Secondary granulopenia or malignant neutropenia may result from enteric fever and other exanthemata, local infection, poisoning by benzene or arspheamine, irradiation by x rays or radium, aplastic anaemia, splenic diseases, etc. Various workers have reported that the intramuscular and intravenous injection of pentose nucleotides transforms the prognosis in agranulocytosis from unfavourable to favourable.

The manufacturers state that "pentide" has been tested biologically and found not to produce any toxic reaction. Its dosage is 10 c.cm. intramuscularly every day until there is definite improvement. For intravenous injection, which is advised during the first four days, 10 c.cm. of the solution should be diluted with distilled water to the strength of 0.8 per cent., and the resulting 100 c.cm. of the dilute solution given daily in addition to the intramuscular doses. The price of "pentide" is 15s. per 25 c.cm. vial. A leaflet discussing this treatment more fully will be sent on application to the manufacturers.

THE EDUCATION OF PARTIALLY SIGHTED CHILDREN

The Board of Education has issued an important report of an inquiry into the problems relating to partially sighted children.¹ It is the report of a committee set up in 1931 by Sir George Newman, the chief medical officer of the Board. Of the eleven members constituting the committee no fewer than seven were non-medical, albeit men (and two women) of distinction; of the four doctors two are officers of the Board, one a medical officer of health, and only one an ophthalmic surgeon, Mr. Percy Flemming. In a problem so largely medical and ophthalmic there would seem to be some risk of lack of weight on the medical side. Nevertheless, the committee was a good jury, and has produced a report that is excellent, and one that will be of undoubted value both to educationists and to school medical officers.

HISTORY

Special provision for the training of children who are partially sighted is of recent origin. There were schools for the normal and schools for the blind. Occasional grumbles were heard at the difficulty of providing for the partially sighted, but nothing was done until the start of the London experimental "myope class" in 1908. As the report states: "The initiation and development of this system of special education for partially sighted children in London, which gave the lead to the whole country, was due to the enterprise and foresight of Mr. Bishop Harman, ophthalmologist to the London County Council, and to Dr. James Kerr, school medical officer for London." The success which attended this scheme of special education for the partially sighted led the London County Council to extend it to other districts, and in 1911 it received the sanction from the Board of Education to establish special classes for an additional hundred children. In authorizing this provision the Council made it clear that it had definitely adopted the policy of educating the partially sighted child as a sighted and not as a blind child.

The rapid spread of these special schools over the world during the past twenty-five years is evidence of their need, and the need for a committee that would sort out the experiences of those who have developed them. A new scheme of education of this sort must inevitably give rise to varieties of experiment, according to local conditions, which might be illuminating.

NOMENCLATURE AND STANDARDS

On the name of these schools the committee came to the definite conclusion that the early official term "partially blind" was bad. "Myope class," the common name in England, is considered too limited, since there are pupils who are not myopes. "Sight-saving classes," the usage of the U.S.A., is considered to claim too much. The preference of the committee is for schools for the "partially sighted."

Dealing with ophthalmic standards for the selection of children for these special schools it is recognized that myopia is by far the most important and frequent single condition which leads to admission. The reasons for the need of care in the education of myopes are considered in detail. Myopia is, for the most part, due to faulty growth of the eye, which manifests itself in school life. It is commonly considered that faulty posture in reading and writing, poor illumination, and excessive convergence of the eyes, such as may occur in reading small print or doing fine needlework, play an important part in increasing myopia. Such conditions are held to be only too common in schools. On the other hand, the committee had evidence from ophthalmic surgeons that rapid progress of myopia may be arrested if all close work is stopped, and at the same time attention is given to general health; though this finding was not without exceptions. There is

¹ Board of Education: Report of the Committee of Inquiry into Problems Relating to Partially Sighted Children. London: H.M. Stationery Office. 1934. (2s net, postage extra)

evidence that the regime of the school for the partially sighted, by the elimination or reduction of factors causing undue stress on the eyes, has some influence in decreasing or arresting the progress of myopia, but that this decrease or arrest is not always permanent.

Some witnesses held that the educational restrictions imposed by attendance at a special school for the partially sighted were not justified by the results attained. The committee sought to balance these opinions. The conclusions arrived at were these:

1. If the eyes show fundus change, indicative of a serious condition of myopia, the child should always be admitted to a special school.
2. In the absence of signs of such fundus changes the child should usually be admitted to a special school if (a) after repeated examinations it is found that the myopia has been increasing at a rate of more than one dioptre per annum; (b) after a period of slow rate of increase or apparent arrest it is found that there is a sudden rise in the rate of progress to more than two dioptres per annum.
3. The actual amount of myopia should not be the sole factor in determining whether a child should be sent to a special school.
4. The age of the child must be taken into account. The younger the child the more serious are factors such as degree of myopia present and the rate of progress of that myopia. In doubtful cases the existence of a history of myopia in the family may be a deciding factor.
5. Myopic children with a visual acuity after correction of 6/24 or worse should be admitted to a special school, though the majority of these will probably fall within Category 1 above.

Children suffering from damaged eyes due to the disease should not be admitted to these schools so long as there is any remaining inflammation. When the disease is quiescent and the vision is reduced by scarring it is considered that it will probably be found, as a rule, that children with a visual acuity after correction of 6/24 or worse, with a near vision of J8 or J10, should be sent to a special school. Cases of optic atrophy are peculiarly difficult to assess; the determination must be made on the expected rate of progress of the degenerative change and the risk of blindness.

SELECTION OF CHILDREN

The ascertainment of partially sighted children is one that concerns first the system of school medical inspection. Even if that be well arranged and carried out there is still risk of missing dangerous cases, owing to the fact that vision tests are not carried out until the child is 8 years of age. The committee suggests a test at an earlier age.

"The next problem is to divide these cases into those who, after treatment, can receive education without handicap or detriment in the ordinary school, and those whose visual defect renders it necessary for them to be educated in a special school for the partially sighted. The ophthalmic principles which should govern the selection of the latter have been fully discussed in the preceding section. The application of them calls for special knowledge and experience in ophthalmology. It is essential, therefore, that the selection of children for admission to a special school for the partially sighted should be made on the principles set out above and only by specialists in ophthalmology."

THE MAGNITUDE OF THE PROBLEM

A considerable effort was made to determine the magnitude of the problem. The variety of factors that influence the ascertainment of partially sighted children in different areas renders it very difficult to estimate, from the figures submitted by those areas, the total number of such children in the whole country. But it is held reasonable to suggest that the proportion of partially sighted children in England and Wales, if selected on the basis of the committee's standards, would be not less than 1 per 1,000 children on the school registers, representing approximately the figure of 6,000.

PERIODIC EXAMINATIONS

The committee comments on the tendency in certain areas to admit a child to a special school and there keep him for the remainder of school life. It is essential—more particularly in cases of myopia—that examination by an

ophthalmic surgeon should take place at periodic intervals of not less than six months, both of those in the special schools and of those who may have been transferred from the special school to the ordinary school. To effect this it is necessary to have some co-ordination between the work done by the ophthalmic branch of the school medical service and that in the special schools, a linking up which can be brought about if the same ophthalmic surgeon be appointed in charge of both.

There is an excellent chapter on the care of the children admitted to the special schools. The committee regards the establishment of schemes to secure continuous ophthalmic supervision of partially sighted children after they have left school as a matter of the highest importance, and is of the opinion that, given good will and co-operation between the various public and voluntary agencies involved, an effective and efficient system could be provided to cover the country.

EDUCATIONAL PROBLEMS

Next the committee sought to reach conclusions on much more difficult problems. First, the type of special school. The whole weight of the evidence was against any association with schools for the blind. Whether or no the special schools should be self-contained units or recognized as part of the normal school has been keenly contested. The committee concludes that the importance of educating partially sighted children in order to fit them to live their life among the sighted is a strong argument for the closest possible association with fully sighted children throughout their school life. After balancing the advantages of segregation and non-segregation systems, and recognizing fully the difficulties which must be overcome and the prejudices which must be broken down, the committee recommends that the education of partially sighted children should be conducted, where possible, in special classes attached to, and forming an integral part of, the ordinary school.

The curriculum presents its problems. On the one hand there are the risks to the sight, and on the other the loss to the child of the normal full curriculum. "One very influential school of thought holds that because of the inevitable danger to the eyesight of myopic children which the constant use of books entails—a danger none the less real because the full effects may not accrue until middle age or later—it is the duty of those who are responsible for the education of myopes to discourage by all means in their power the habit and the love of reading. Another school would allow the use of books under carefully guarded conditions, holding the view that the risk of impaired vision is not, as a rule, great enough to justify the loss of educational opportunities caused by deprivation of books. The protagonists of these conflicting views are irreconcilable. The committee recommends that under the age of 8 years books should be very sparingly used, and the main work be done on blackboards, and, in so far as it is advisable to supplement this with books, these should be printed in 24-point type. For older children this type or 18-point need not be prohibited entirely. Consideration is given to the use of handiwork and physical training, and to the most necessary training of the teachers for these classes.

A separate chapter is devoted to the finding of suitable employment for these children after school age, the methods of finding work, occupations, and supervision. It is disquieting to learn that the partly sighted are more likely than other young persons to fall into the ranks of the unemployed, becoming a section of the unemployed with a particular handicap. Young employees with good personal qualities can sometimes work their way into permanent posts, even from first employments which are intrinsically of a blind-alley character. The moral of the situation is that, without all-round ability and strong personal qualities, partially sighted children are likely to be among the first to suffer when young labour is being turned out of employment. The committee is averse to specific vocational training, such as is common for the blind; the aim should be to educate them, as far as possible, to compete on equal terms with other people.

BLADDER-NECK OBSTRUCTION

The question of bladder-neck obstructions, dealt with by Mr. Duncan Morison in our present issue (p. 53), is an important one. It also formed the subject of discussion at the fifth Congress of the International Society of Urology in London this year, the introductory papers being read by Professor Marion (Paris), Professor Weijtland (Amsterdam), and Mr. Kenneth Walker (London). The prominence given to the subject of late is explained by the fact that although the existence of bladder-neck obstructions apart from prostatic enlargement has long been recognized by urologists, the pathology and the relation of this disorder to other abnormalities in that region are imperfectly understood. Not only are different names attached to what is essentially the same pathological condition, but also separate pathological conditions are included under the same name. This has naturally resulted in much confusion of thought, and therefore the concise review given by Mr. Morison should prove a useful aid to those who have been bewildered by the copious and conflicting literature that has sprung up around the subject.

Reduced to its simplest terms, it may be said that the symptoms produced by lesions of the bladder neck are due to its inability to open at the moment of micturition. In order to emphasize this point, the French urologist, Professor Legueu, has coined the term "dysectasia" as a descriptive heading under which all cases of bladder-neck obstruction may be placed. This is a useful addition to our nomenclature, for the term "dysectasia" is comprehensive enough to include such varied conditions as sclerosis of the bladder neck, glandular hyperplasia, adenoma, muscular hypertrophy, and the type of case described by Marion as congenital "maladie du col." In all these conditions, the resulting disability is essentially the same—namely, an inability on the part of the bladder neck to open, with, as a consequence, failure of the detrusor to expel the contents of the bladder. It is not surprising that the condition of dysectasia should frequently have provided a puzzle for the clinician. Faced with a patient who displayed all the symptoms of prostatic obstruction and yet had no enlargement of that gland, a diagnosis could only be based on an elimination of any other condition, and on the cystoscopic appearance of the bladder neck. Can it be wondered at that the medical man whose experience of cystoscopy was limited failed more often than not to discover the thickening and raising of the posterior lip of the bladder outlet that is characteristic of bladder-neck obstruction, and regarded the case as one of bladder atony? The

treatment adopted in order to improve the tone of the bladder wall naturally failed to have any results in the presence of obstruction, and in the end the patient was condemned to catheter life or permanent suprapubic drainage.

The fate of a patient in whom the existence of obstruction was recognized but considered to be due to a small obstructing prostate, although better, was by no means to be envied, since he was generally subjected to a major operation instead of to a procedure of comparatively minor importance. Every surgeon must have had the experience of opening the bladder in the expectation of finding a prostate that could be enucleated, and discovering a fibrosed gland that defied all attempts to shell it out. In such cases, after much exertion, a small fragment of tissue has been torn out from the region of the bladder neck and the patient returned to bed labelled "fibrous prostate" or else "malignant disease." Many of these mistakes have arisen from a failure on the part of the profession to recognize the existence of a form of dysuria due to an altered condition of the bladder neck rather than to a lesion of the underlying prostate. The numerous papers and reports of discussions that have of late years appeared on this subject show that not only urologists, but general surgeons, are beginning to differentiate between micturition difficulties dependent on an obstructing prostate and those caused by a lesion of the bladder neck. Provided the correct diagnosis be made, the results of treatment are excellent, whether this lies in the direction of an open operation or of a perurethral resection. To the majority of urologists the latter method commends itself, because it avoids the necessity for opening the bladder in order to remove a small amount of tissue from its neck. Marion, almost alone among experts, shows a preference for the more extensive operation on the ground that open resection is in his opinion more likely to yield a complete and lasting cure. Although the verdict of such an expert must carry weight, it would seem reasonable to employ perurethral methods whenever they are possible. So many improvements have been made in this method of operating of late years that even prostates of considerable bulk can, if necessary, be resected by means of such an instrument as the McCarthy electrotome. Compared with such a feat the removal of a fibrous bar is a trifling matter; and it is only when the fibrosis is widespread, and involves not merely the whole circumference of the bladder outlet but also the tissues of the prostate, that an open operation becomes necessary.

Although in the hands of an expert perurethral resection of an obstruction at the bladder neck is an operation that entails very little discomfort to the patient and practically no danger, its performance demands considerable knowledge and experience on the part of the operator. Even when it is performed by a surgeon accustomed to the use of a cystoscope, serious mistakes may be made. A survey of the after-results obtained in different urological clinics in America will

reveal the fact that complications and accidents occurred far more frequently among the earlier cases. With greater skill in the use of the resectoscope, and greater knowledge of the amount of tissue that had to be removed in order to re-establish free micturition, these complications and accidents became rarer and rarer, and good results were obtained with less and less discomfort to the patient. What is true of perurethral resection of enlarged prostates is equally true of perurethral resection of bladder-neck obstruction. The electrotome in the hands of anyone inexperienced in its use is an instrument that is capable of inflicting much damage, and cases of recto-vesical fistula, incontinence of urine, and even of perforation of the peritoneum, are by no means unknown.

THE HEALING OF A WOUND

Sir Andrew Macphail, who is professor of the history of medicine in McGill University, has contributed a valuable and timely article to the *Quarterly Review* (January, 1934), which is reprinted in the *Canadian Medical Association Journal* for June. The article is entitled "The Healing of a Wound," and begins with the somewhat startling statement—which is nevertheless true—that until recently animals managed the business better than human beings. Animals have their own methods of dealing with a wound. Rest is their remedy. They are not led astray by wrong theories. If they are denied the use of instruments they are spared the abuse of them and the use of things that do more harm than good. The history of the healing of a wound, writes Sir Andrew, is the history of surgery. For the modern surgeon under 40 years of age a wound has no existence; the healing is inevitable, governed by a law of nature. Accustomed to wounds made by himself in ideal surroundings, with his chosen instruments, upon tissues prepared in advance, healing is to him a natural process. Failure to heal is now the miracle.

Lulled into false security the world war brought us a rude awakening, and surgeons quickly learned the truth of that saying of Heraclitus that "war is the father of everything." The civil surgeon was astonished at the vast dirty wounds of war, and we saw a feverish harking back to the free employment of antiseptics. Asepsis in the field was like a lost tradition. Sir Andrew Macphail recalls in vivid words how the drainage of septic joints, their irrigation through tubes, the application of short splints to long limbs, meant amputation at the Base. Operators who from their training must close every wound by sutures, and yet were prevented by their knowledge and conscience from closing them, employed an emulsion of bismuth, iodoform, and paraffin, and so evolved the delayed primary suture. But their scientific training had given them the flexible mind that adapts itself to a new experience. Soon they had discovered that the proper surgery of the front area was to clean the wound, ruthlessly cut away all dead and dying tissue,

check bleeding, and pack the cavity with some light material soaked in a harmless fluid. Speed in evacuation from the field to the base finally solved the problem. The long Thomas splint held its own to the end, and was carried by the regimental bearers. Blood transfusion was practised even in the trenches.

Nature has two ways of healing a wound: by first intention and by suppuration. The history of suppuration unfortunately is the history of surgery. A few great surgeons in all ages designedly healed the wounds of their patients by first intention; but the accepted teaching was that pus must be generated in every healing wound. It is hard now to believe that faith in the beneficence of suppuration prevailed almost to our own time, and that pus could be called laudable. But so it was, and a surgeon felt happy if his wound produced a thick matter with a slightly mawkish smell. He was not even perturbed if a slight blush, which would now be called erysipelatous, spread along the edges of the wound, for he looked upon it as a harbinger of more rapid healing. For him there was pus that was not laudable—thin, ichorous pus, which he knew was too often followed by fever, sleeplessness, and death. Sir Clifford Allbutt said thirty years ago: "In the third quarter of the nineteenth century the apothecary of a large hospital showed me a row of amputations with stumps pouring out pus in cataracts upon the cushions, and exclaimed: 'That, Sir, is what I like to see; nothing so wholesome in a wound as a good discharge of laudable pus!'"

The long history of the healing of a wound, so graphically outlined by Sir Andrew Macphail, falls into two periods, the dividing line between them drawn within the lifetime of some who are still with us. It is marked by Lister's work and teaching. Two other divisions may be made: one at the point where Ambroise Paré substituted the ligature for the red-hot knife and cautery; the other with the discovery of anaesthesia. But the work of Lister was not a casual and isolated discovery. It was the slow result of long experience based upon scientific principles. The pathology of the Hunterian school taught that every organ and tissue had its own way of repair, that the healing of the skin and muscles was easy, that the process in bone was slow and dangerous, and that the serous membranes and the veins were in a class by themselves, most sensitive to injury and difficult to repair. Lister was among the first to assert that the healing of all tissues was uniform and constant if germs were excluded; that repair was governed by a scientific formula. His method, elaborated in the most minute detail, was based upon the work of Pasteur in widely different but allied fields of research. Lister's discovery met first with neglect and then with opposition. Even in Scotland it was received with contemptuous criticism, and James Y. Simpson dismissed the germs as mythical fungi. The whole question of spontaneous generation was involved; it was only disproved by Tyndall after the labour of a lifetime, and of Tyndall we still await a satisfactory biography. The revolution

in the healing of wounds spread slowly; on the Continent sooner than in Great Britain. Volkmann in Germany, Bloch in Denmark, Lucas-Championnière in France, were quick to appreciate the value of the new work. It reached Billroth through Volkmann; but not until 1879, more than twelve years after the discovery, did the master surgeon in Austria send von Mikulicz-Radecki to King's College Hospital in London to verify the reports he had already received. The good news and the actual practice were taken to America by four Canadians, who had been Lister's house-surgeons, and of these John Stewart, who was for long dean of the medical school at Dalhousie University at Halifax, only died on December 23rd of last year.

MARIE CURIE

The death of Marie Curie has not only deprived science of one of its foremost original investigators, but the medical world of a great benefactor. To many of us it seems no long time since Roentgen's discovery of the x rays aroused widespread interest. It is doubtful if any scientific discovery has ever attracted so much popular attention; probably because it appealed to that most universal of human characteristics—curiosity. It was while the interest aroused by Roentgen's discovery was at its height that Becquerel reported the spontaneous emission from uranium and its compounds of radiations similar to those produced by the x -ray bulb; and to this discovery of radio-activity Professor and Madame Curie were indebted for the line of research which led to the discovery of radium. Shortly after the announcement of Becquerel's experiments with uranium, it was observed that naturally occurring uranium ores exhibited a higher degree of radio-activity than could be accounted for by the percentage of uranium present. Obviously some substance or substances must be present which exhibited radio-active properties in a more marked degree than uranium itself. It was to the isolation of these that Marie Skłodowska Curie and her husband devoted themselves, and, as is well known, their researches were crowned by the discovery of radium, at first in the form of its salts and finally as the element. This is not the place for an account of Madame Curie's scientific work; but the extent to which medicine is indebted to her discovery can hardly be overestimated. Radium—either alone, or, more generally, in conjunction with high-voltage x -ray therapy—is now universally recognized as the most appropriate treatment in many forms of malignant disease. Two forms of this especially which were formerly treated by extensive, mutilating, and but too often ineffectual surgical methods, have been found to respond well to radiation therapy. We refer, of course, to carcinoma of the tongue and of the cervix uteri. Even if the cases are too advanced to allow of any hope of a permanent "cure," the relief of symptoms which follows radiation treatment often appears little short of magical. It is perhaps only those who remember the "incurable" cancer wards of thirty years ago who can appreciate the change which has been wrought by radiation therapy in alleviating the distress of incurable cases. Equally, with early diagnosis—and this is essential—radiation treatment in

many cases holds out the best possible hope for the eradication of the disease; and this with an almost negligible operative mortality. Madame Curie has a worthy memorial in this country in the Marie Curie Hospital at Hampstead, in the work of which the late Sir Walter Fletcher was so deeply interested, and where results have been obtained at least equal to those of the foremost Continental clinics.

HEALTH WORK OF THE LEAGUE

On July 10th an international course in malariaology opened at the Institute of Malariaology in Rome under the auspices of the Health Organization of the League of Nations. This course is conducted under the direction of Professor Bastianelli, director of the Institute of Malariaology, with the assistance of the experimental antimalarial station (Professor Missiroli, director). Lectures are being given by experts in malaria from different countries. The course covers the period from July 10th to September 10th, and will be followed by students from nine countries (these students are holders of scholarships from the Health Organization or from their Governments)—Bulgaria, France, Italy, Peru, Persia, Rumania, Spain, Turkey, and Yugoslavia. The malariaological institute in Rome and the antimalaria experimental station possess large collections of valuable demonstration material. They have the further advantage of being situated in the neighbourhood of classic malaria-ridden districts. Under these conditions the teaching can be both theoretical and practical. The course will include visits to the various experimental stations and antimalaria stations, in different endemic and hyperendemic districts, as well as inspection of districts which have been rendered healthy or are in process of being rendered healthy. The Committee on the Radiology of Cancer will meet in Zurich from July 21st to 23rd. It will examine the progress made in the inquiry which the Health Organization undertook in 1930 with a view to rendering comparable the results of different methods employed by radiological institutes and gynaecological institutes in the treatment of cancer of the uterus by radium and x rays. The committee will draw up plans for continuing this inquiry. The method followed has been that the institutes taking part compile daily clinical reports for each case which they treat. Figures and observations are recorded according to certain agreed rules.

CENTENARY OF THE MANCHESTER MEDICAL SOCIETY

On October 1st of this year the Manchester Medical Society will have completed a century of activity, and arrangements are being made to celebrate the event. The president for the year is Dr. E. Bosdin Leech, whose uncle, the late Dr. D. J. Leech, was president in the society's jubilee year. The chief items in the programme which is being drawn up are the president's address, the publication of a history of the society, an exhibition of objects of general and medical historical interest, and a dinner. Dr. Leech's commemorative address will be given on Wednesday, October 3rd, Wednesday being the day of the week on which the ordinary meetings of the society have been invariably held for one hundred years. The history (written by

Dr. E. M. Brockbank) will, besides being a record of the society's activities, contain important biographies of John Hull, the first president, and of Caesarean section and phlegmasia dolens fame; and Thomas Windsor, prince of book collectors, who made the society's library what it was and who later transferred his energies to the surgeon-general's library in Washington. The exhibition will be of objects of general interest, chiefly in connexion with the medical history of the town during the society's lifetime; books from its old library, recently presented to the University of Manchester; portraits of prominent local medical men, and illustrations showing the growth of the older hospitals, etc. It will be arranged, through the courtesy of the Lord Mayor and the Libraries Committee, in the fine room designed for such a purpose in the new central library, and will be opened formally on October 1st. It will, in fact, be the first exhibition in this room. The dinner will be held on the evening of October 3rd, and many distinguished guests from near and far have accepted invitations to it. The secretary of the society (c/o the University, Manchester) will be glad to hear from any of its old members who may have objects of interest bearing upon its history for exhibition, or who would like to attend the celebration meeting.

THE L.C.C. AND THE STERILIZATION REPORT

The London County Council on July 3rd discussed the report of the Departmental Committee on Sterilization, which was issued in January last.¹ The Hospitals and Medical Services Committee had no observations to offer on the report, but the Mental Hospitals Committee had decided, by a majority (25 votes to 15), to approve the Departmental Committee's recommendation that, subject to safeguards, voluntary sterilization should be legalized in the case of any person who is mentally defective or has suffered from mental disorder, or is likely to transmit either incapacity, and any person who suffers from a grave physical liability or is likely to transmit it. The Mental Hospitals Committee stated that, since it was the view of the Departmental Committee that defectives in institutions should not be considered for sterilization unless they were capable of taking their places in community life, the number of defectives who might be sterilized would be strictly limited. The committee was advised that in London there were more defectives in institutions than under statutory supervision in their own homes, and that, of the defectives in institutions, only a small percentage became fit to "float" in the community. With regard to normal persons who were believed to be likely to transmit mental disorder or defect, it would presumably be necessary to establish, by means of pedigrees, that mental disorder or defect was inherent in the family. As the main point in the recommendation was that sterilization should be voluntary and not compulsory, it was clearly impossible to gauge the number of cases of mental disorder or defect, or carriers thereof, in London who might submit themselves for such an operation. The General Purposes Committee, whose responsibility it is to bring forward a recommendation, if any, decided that the knowledge and facts in possession of the Council were not sufficient to warrant

it expressing an opinion on the recommendations of the Departmental Committee. A motion calling for the support of the Council for the recommendations of the Departmental Committee was proposed in the Council by Mr. Eric Hall, a Municipal Reform member, and seconded by Mrs. Bolton, a Labour member. Mr. Hall pointed out that the Departmental Committee was a very strong one, and had come to a unanimous decision. The voluntary aspect was emphasized, and the position of those to be treated was hedged around with every possible safeguard. There was no suggestion of compulsion in the report, and there was no ground for regarding voluntary sterilization as the thin end of the wedge. From 1926 to 1929 the Council was inundated with recommendations from different county authorities in favour of sterilization. Mrs. Bolton, in seconding, said she did so on eugenic and humanitarian grounds. The percentage of mental defectives was rising, and there was high fecundity among the feeble-minded, while at the same time, among responsible and healthy people, the principle of family restriction was growing. At present, while sterilization was at the command of the wealthy, it was only with the greatest difficulty that a poor man with an inherited physical or mental disorder could find a hospital willing to sterilize him. Mr. L. Silkin, a Labour member, opposed the motion. The whole case for sterilization, he said, was based on the theory that mental deficiency was hereditary; if that could not be established the case fell to the ground. He was not satisfied as to that basis; it might very well be that environmental factors which had caused the parents to be defective had also produced mental defects in the children. Sir Oscar Warburg, a Municipal Reform member, said that the Council was not an appropriate body to balance the various factors, and the same view was put forward by Mr. Herbert Morrison, the Labour leader of the Council, who said that on the evidence before them they did not know enough to express an opinion one way or another, and unless they were absolutely sure they had no right to use public services for the purpose of tampering with human beings. Mr. J. H. Macdonnell feared that if sterilization were permitted the poor would be the subject of experiment. On a free vote in the Council, the party whips being taken off, it was agreed, by 63 votes to 44, to express no opinion on the recommendations of the Departmental Committee.

ICTERUS GRAVIS NEONATORUM

One of the results of the increased interest shown of late years in disorders of the blood and the blood-forming apparatus has been the closer study of diseases which at first sight have little to do with this system of the body, but which in fact are intimately related to it. In a recent article² Drs. J. C. Hawksley and R. Lightwood describe the clinical and pathological features of the disease known as icterus gravis neonatorum, which is apparently one form of acute haemolytic anaemia in the newborn, in close association as regards aetiology with hydrops foetalis and congenital anaemia. Occurring usually in families, often where the previous children have been stillborn or affected with jaundice, anaemia, or hydrops, this type

¹ See *British Medical Journal*, 1934, i, 156 and 161.

² *Quart. Journ. Med.*, April, 1934, p. 155.

of jaundice makes its appearance within the first two or three days, and, rapidly deepening, leads on to drowsiness, anaemia, dyspnoea, enlargement of liver and spleen, and death, often with convulsions, in a large number of untreated cases. The important point clinically is the severe anaemia present, often masked by the jaundice but demonstrable in the mucous membranes. Blood examination at this period shows the severity of such anaemia, counts lower than half a million red cells per cubic millimetre having been recorded. The large number of nucleated red cells seen, the presence of reticulocytosis, and the positive indirect van den Bergh reaction all indicate the similarity of this disorder to the group of "destructive" or haemolytic anaemias of later life. The striking pathological finding in these cases is the widespread blood-forming centres outside the bone marrow, indicating clearly the body's attempts to compensate for a blood-destructive process. That, at any rate, would appear to be the current view in this country, though authors elsewhere have postulated a primary upset in the blood-forming apparatus resulting in the appearance in the circulating blood of young and unstable cells which undergo rapid haemolysis. Whatever the exact causation of the malady, the main point to note at this stage is that treatment can be applied to bring the haemolytic process to a stop, and what was once a disease with an extremely high mortality can now be dealt with satisfactorily. The use of human serum, as suggested by Hampson, while effective in some instances in daily doses of 5 to 15 c.cm. until bilirubin begins to disappear from the blood, is not so certain a method as that advocated in the present paper—namely, the transfusion of citrated whole blood. Either parent may be the donor, and direct matching of donor's cells against the baby's serum is recommended. The size of the transfusion is on the basis of 10 to 15 c.cm. of blood per pound of body weight, and it has to be repeated at intervals of four to seven days until the red cell count is maintained at or about four million per cubic millimetre. The need for repeated transfusions is well illustrated in a case lately recorded¹ by Dr. W. R. F. Collis from Dublin. Here a baby, in a family where four previous children had died with deep progressive jaundice, became jaundiced forty-two hours after birth, and finally recovered after four transfusions, interspersed with, altogether, twenty-two injections of human serum over a period of about five weeks. The anaemia in this patient was not so marked as in some of the recorded cases, but the red cell count on occasions was below two million per cubic millimetre.

AN EXAMPLE OF MEDICAL CHARITY

In 1911 the medical men of Barnstaple, Devon, appealed to the profession on behalf of Dr. C. M. Cooke, whose career was cut short by blindness at the age of 47.² To that appeal the profession responded magnificently, for there was subscribed the sum of £2,378 3s. 5d., which, after deduction of the expenses and an immediate cash payment to Dr. Cooke, left some £2,000 for investment. Of this £1,000 was spent in the purchase of a life annuity for Dr. Cooke and the remaining £1,000 invested. The generosity of the pro-

fession enabled Dr. Cooke to enjoy this annuity for over twenty years, until his death in the early part of this year. There remains, after the payment of expenses, a sum of £920, and Dr. J. R. Harper of Barnstaple, who was the moving spirit in the original appeal, and, with his fellow trustee, Mr. Gerald Oerton, solicitor, has been responsible for the administration of the fund throughout the past twenty years, seeks to dispose of the balance in a way which he believes will give expression to the intentions of those who gave so generously in 1911. He has handed the sum of £925, an amount which is in itself a tribute to the careful organization and administration of the fund, to the Charities Fund of the B.M.A. for distribution to the Royal Medical Benevolent Fund, which carries the major burden of medical charity on its shoulders, and to the Sir Charles Hastings Fund, from which grants and loans are made to medical men in urgent and immediate need. Not only will this contribution be unusually welcome to medical charities at a time of considerable need, but it may prove a reminder that medical men and women are not unresponsive to an appeal on behalf of a fellow doctor when they are brought face to face with the facts.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* and *Épitome* have been prepared and will be ready shortly; they will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or all of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

The British Pharmacological Society held its annual meeting at Oxford on June 29th and 30th, under the chairmanship of Professor J. A. Gunn. Three new honorary members were elected: Professor Tiffeneau (Paris), Professor W. Straub (Munich), and Professor Heubner (Berlin). Previously elected honorary members were Professor J. J. Abel (Baltimore) and Professor Hans Meyer (Vienna).

A preliminary conference on official and non-official co-operative action, as suggested by the League of Nations Inquiry in the East, has been organized by the Joint Standing Committee of the British Social Hygiene Council and the Conference of British Missionary Societies. It will be held on Wednesday, July 25th, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.; with the Earl of Lytton in the chair. The objects of the meeting are: to consider reports on existing methods of co-operation between government and non-official organizations in combating traffic in women, in the rehabilitation of victims of the traffic, and in educating public opinion on the social value of the modern methods of combating commercialized prostitution and venereal disease; and to discuss what measures can be promoted by, and among, non-official organizations in the East to prepare for the suggested conference under the aegis of the League of Nations.

NOTIFICATION OF TUBERCULOSIS IN GREAT BRITAIN

A HISTORICAL NOTE

BY

SIR ARTHUR NEWSHOLME, K.C.B., M.D., F.R.C.P.

My attention has been drawn to a paragraph in Sir Robert Philip's "Musings in the Garden" (*British Medical Journal*, June 23rd), in which he quotes from my *Prevention of Tuberculosis* (Methuen, 1908) a statement against the adoption on a national scale of compulsory notification of phthisis, and goes on to remark that this procedure became the law of the land in 1912. It has been inferred from the quotation and statement that, although in 1908 I became the chief medical adviser of the Central Government in public health matters, the adoption of compulsory notification was carried through in 1912, notwithstanding, and not—as was the fact—in consequence of my official counsel and urgent action.

I assume that Sir Robert did not intend this inference to be drawn; but evidently it is important to place on record the correct history of the long-continued strenuous efforts made by a number of medical officers of health and other social workers, including myself, to secure first voluntary, and in due course compulsory, notification of every case of phthisis. This history is partially stated in the chapter in my *Prevention of Tuberculosis*, 1908, from which Sir Robert Philip's quotation—which apart from its context is misleading—was taken. The history will be given more completely in my *Recollections of Fifty Years in Public Health*, which is nearly ready for publication.

To understand the problem we must recall its setting. The history of the notification of the chief acute infectious diseases is one of slow conversion of public opinion and especially of medical opinion from opposition to favour or at least to acceptance of this intrusion, in the public interest, into the confidential relationship of the family doctor to his patient.

Prolonged agitation had gone on for many years before the late Dr. Sergeant secured the first local Act for the notification of acute infectious diseases in Bolton, Lancs. Other towns gradually secured the same powers; then in 1889 a more general Act was passed giving local option, and in 1899 an Act of Parliament made compulsion universal in all districts. A similar history attaches to the enforcement of compulsory notification of births within thirty-six hours. Huddersfield (Dr. Moore) led the way in 1905 by a local Act, other towns followed slowly. Then a more general permissive Act was passed in 1907, and compulsion became universal in 1915. A like history holds good for the notification of tuberculosis, though in this instance the difficulties involved in overcoming the opposition of the leaders of the medical profession and of its public health service were almost immeasurably great.

I could fill several pages with illustrations of the persistent opposition to even voluntary, much more to compulsory, notification of phthisis, but I must content myself with quoting the position taken at the meeting in Marlborough House on December 20th, 1898, H.R.H. the Prince of Wales (afterwards Edward VII) being in the chair, to inaugurate the recently constituted National Association for the Prevention of Tuberculosis. The chief resolution of the meeting was proposed by the Marquess of Salisbury, who made the following, among other remarks:

Nothing is more striking in the luminous statement of Sir William Broadbent or in the discussion following than the absence of all desire that the powers of the law should be brought into operation to carry out the objects of the Asso-

ciation. . . . This is a snare which they will carefully avoid. They must be content with preaching the salutary doctrine which they hold, and must not think of applying to the secular arm.

This statement appeared to embody the unanimous view of the conference, at which the chiefs of the medical and veterinarian professions spoke.

At this point I am compelled to mention my own share, as well as that of others, in overcoming the persistent opposition to the notification of tuberculosis. But first let me make it clear that the early and continuous efforts of Niven and others like myself to secure notification of tuberculosis were not made merely to enable social investigations of housing, etc., to be undertaken. For this purpose anonymous notifications would have sufficed. There was deliberate intention to institute additional precautionary measures against infection and all circumstances favouring it, to an extent which was not practicable (or would not be practised) in many instances if the confidential relation between the patient and his doctor remained undisturbed. It was this implication which naturally—and, I may add, properly—gave weight to the persistent objection to compulsory or even voluntary notification.

Dr. James Niven, then M.O.H. for Oldham, was the first, in 1894—note the year—successfully to persuade the doctors of that town to favour the voluntary notification of their cases of phthisis to him, but the town council declined to endorse the proposal. Dr. Hermann Biggs later in the same year succeeded in a similar proposal for the city of New York. In 1899 I was successful in establishing the first system of voluntary notification of phthisis in this country, in the town of Brighton. This was the culmination of prolonged advocacy. In the same year Dr. Niven, then M.O.H. for Manchester, persuaded the City Council to adopt the same course, thus succeeding after his earlier attempt in 1894. I contributed various papers on the subject, and prior to 1908 had obtained the passing of resolutions in favour of voluntary notification of phthisis, at meetings of the Society of Medical Officers of Health, of the Sanitary Institute, and at the 1901 International Congress on Tuberculosis. In proposing these resolutions I deprecated premature attempts at notification—that is, attempts when the local authority did not yet possess an organization for securing improved care of the notified patients.

In 1908 I was appointed Principal Medical Officer of the Local Government Board, and was confronted with the task of securing a complete reversal in this respect of the past policy of the Central Health Department of England. The arguments against compulsory notification have never been more forcefully stated than in Sir R. Thorne's Harben Lectures in 1899. He "felt certain that the compulsory notification of phthisis is calculated to retard the very object which they [its advocates] have in view." Sir William Power, in his introduction to Dr. Bulstrode's report on sanatoria in 1908, cautiously indicated the possibility of further local experimentation in notification. He referred to Sheffield, which, under the leadership of Dr. (now Sir John) Robertson, had already, at the end of 1903, secured the local enactment of compulsory notification of phthisis, associated with powers which "expressly dissociated administratively phthisis and everyday infectious disease." And Sir William mentioned the experience of Brighton "as indicating that where obvious personal advantages accrue to the patient—where he is not harassed in a social sense . . . a system of voluntary notification may yield useful results."

It was at this stage that I wrote the sentence in respect of compulsory notification on a nation-wide basis, which Sir Robert Philip has detached from its context, and thus done me less than justice.

I cannot detail here the almost insuperable difficulties encountered in overcoming central official opposition towards compulsory notification of tuberculosis for the entire country. The task to be undertaken was the gradual culmination of the continued and strenuous efforts of Niven of Manchester, Biggs of New York, and the rest of us during many years, and which in Sheffield had already succeeded, thus establishing the right of local experimentation on compulsory lines. Legal authority pronounced that the conditions of the Infectious Disease (Notification) Act could not be extended to tuberculosis. After much struggling this obstacle was circumvented by another procedure, on the strenuous intervention of Mr. John Burns. As a *bouleversement* of past official policy was contemplated, and as, furthermore, many sanitary authorities were still unready for complete systematic administration of notification, I decided that the best plan was to secure enactment of compulsion in successive stages. And in the first year (1908) regulations were framed making it obligatory on all medical officers of Poor Law institutions, and on all district medical officers throughout England and Wales, to notify each case of phthisis under their care. This was followed very soon by the enactment of a similar nation-wide obligation to notify all cases of phthisis attended at any hospital, whether voluntary or official.

The third stage was the issue of regulations enforcing also the notification of cases of phthisis occurring in private practice; and lastly, in 1912 this universal obligation to notify was extended to non-pulmonary as well as to pulmonary tuberculosis. In 1911 the passage of the National Insurance Act, and the gift by the Treasury of over a million sterling for sanatoria, and of half the cost of administration of tuberculosis schemes, made it easy for every local authority to carry out the preventive work which should follow notification; and one had the satisfaction of knowing that the gradual but rapid enforcement of obligatory notification to increasing groups, and at last to the entire population, was a real and not a "paper" reform; the preventive work following it being commensurate with the steadily increasing range of notification. In short, compulsory notification had become universal as soon as there was reasonable prospect that practical measures on a national scale would follow its adoption. But it is my conviction that this could not have been effected so promptly but for the hard work during two decades of medical officers of health, who had demonstrated what could be accomplished when the notification of cases of phthisis was voluntary.

RESEARCH FELLOWSHIPS IN TUBERCULOSIS

The Medical Research Council announces that it has made the following awards of Dorothy Temple Cross Fellowships for 1934-5, under the terms of the benefaction in that name for research fellowships in tuberculosis:

WILLIAM SAYLE CREER, M.B.Liverp., Lady Jones Orthopaedic Research Fellow, University of Liverpool.

ALFRED WHITE FRANKLIN, B.A., M.B.Cantab., M.R.C.P. Lond., Chief Assistant to Children's Department, St. Bartholomew's Hospital, London.

PHILIP D'ARCY HART, M.A., M.D.Cantab., M.R.C.P. Lond., Assistant Physician, University College Hospital, London.

ARTHUR LANDAU, M.B.Capetown, M.R.C.P.Lond., House Physician, Brompton Hospital, London.

ALASTAIR HAMISH TEARLOCH ROBB-SMITH, M.B.Lond., Senior Demonstrator of Morbid Anatomy, St. Bartholomew's Hospital, London.

Dr. Robb-Smith's fellowship is tenable in Germany: the others at centres in the United States.

In addition, the fellowship awarded last year to Dr. GEORGE GREGORY KAYNE for work at centres in Europe, has been renewed for a further period of six months.

BRITISH EMPIRE CANCER CAMPAIGN

ANNUAL MEETING

The annual general meeting of the British Empire Cancer Campaign was held at the House of Lords on July 9th, with the MARQUESS OF READING in the chair. A letter was received from the President of the Campaign, the Duke of York, stating that he had read the eleventh annual report with great interest, and the impression it had made on his mind was twofold: first, that the world of research within the Empire was a beehive of intense activity, and, secondly, that those who were well qualified to judge were satisfied that another swing-forward by the momentum of progress had taken place in no uncertain fashion. His Royal Highness added how gratified he was to hear that the Empire Day appeal had met with such spontaneous and whole-hearted support.

CO-ORDINATION OF RESEARCH

After the members of the Grand Council had been re-elected, on the motion of Mr. STANFORD CADE, the adoption of the annual report was proposed by Mr. CECIL ROWNTREE, who declared that the purposes for which the Campaign was founded were being fulfilled in all directions. One of those purposes was the co-ordination of research and research organizations, not only within Great Britain, but throughout the Empire. The recent step of setting up a panel of international correspondents, whereby there was an accredited representative in each of the great scientific capitals, had materially added to the accuracy and promptitude of their foreign information. The world had done the Campaign the honour of copying its organization, for it was now proposed that an International Cancer Union should be constituted, and a preliminary meeting had taken place in Paris. Dealing with some outstanding features in the scientific portion of the report, Mr. Rowntree said that investigations carried out at the Cancer Hospital and the Middlesex Hospital had suggested the possibility that the ultimate cause of cancer might be something of a chemical nature produced by disordered functions within the body itself. With regard to prevention, there had been a great increase in the knowledge of the pre-cancerous condition, and in particular it appeared likely that there would be a great diminution in the incidence of industrial cancer as a result of investigations into the occurrence of carcinogenic agents in lubricating oils and other industrial materials. On the curative side he mentioned the recent advances in radiation treatment. Partly as a result of the pioneer work done by the Radiology Committee of the Campaign, radium had won its way to safe and successful use and to widespread professional recognition. The radium "bomb" was coming to be regarded as a necessity for all well-equipped cancer centres. The radium position had been eased by the discovery of Canadian ores. Certain kinds of cancer, said Mr. Rowntree in conclusion, occupied hopeful salients, where advance had outstripped the general level, but the line as a whole was advancing. It was not to be expected that some sudden flash of genius could solve the cancer problem in a day.

Mr. RICHARD C. DAVIES, in seconding the report, said that there was a deficit on the year of £15,282. This was due to several causes, among them the fact that part of the normal income had been diverted to the Empire Day appeal. The result of that appeal during the months of May and June amounted to £40,246, apart from certain large donations which were pending. He hoped that the appeal would be a recurring feature of successive Empire Days.

THE GARTON PRIZE

The report having been duly adopted, LORD READING presented the Garton prize (£500) and medal to Dr. H. A. Colwell for what in the unanimous opinion of the judges was the best essay on the biological effects and mode of action of radiations on malignant and other cells; with a second prize (£100) and certificates to Dr.

F. G. Spear, of the Strangeways Research Laboratory, Cambridge, and his associates—Dr. R. G. Canti, Dr. W. H. Love, Dr. B. Holmes, Mr. L. G. Grimmer, and Miss S. F. Cox.

Afterwards the fifty-first quarterly meeting of the Grand Council was held, with Sir HOLBURN WARING in the chair, at which one of the references from the Executive Committee was that the 10 per cent. "cuts" in block grants to institutions be restored for the current year.

STANDARDIZATION OF VITAMINS

INTERNATIONAL CONFERENCE

The second international conference on the standardization of vitamins was held in London from June 12th to 14th, under the chairmanship of Professor E. Mellanby, Secretary of the Medical Research Council of Great Britain. Both first and second conferences were convened by the Health Organization of the League of Nations, and held under its auspices. Experts were present from the following countries: Denmark, France, Great Britain, Hungary, Italy, the Netherlands, Norway, Sweden, and the United States of America.

The report of the earlier conference, published in 1931, recommended for international adoption standards and units for four vitamins (A, B₁, C, and D), adding that these standards should be "provisional for two years": vitamin A, which is necessary for growth, and the absence of which seems to render the organism more liable to infection; vitamin B₁, sometimes known as the antineuritic vitamin, which seems to be necessary to prevent the disease called beri-beri; vitamin C, necessary for the prevention of scurvy; vitamin D, necessary for the prevention of rickets.

Since certain of the standard preparations recommended for adoption were not available for general use until 1932, the second conference was postponed until 1934, at which date two years' experience of the working in practice of the provisional standards was available. The report of the present conference should therefore be regarded as a revision of the report of the 1931 conference. In making its decisions the present conference had at its disposal the results of two years' experience with the provisional standards, and in the interval a number of new facts, of importance in connexion with vitamin standards, had come to light. The provisional standards are widely used throughout the world, but it was the general opinion that certain alterations were advisable.

STANDARDS AND UNITS FOR FOUR VITAMINS

As in the 1931 report, standards and units are recommended in the case of only four vitamins—namely, vitamins A, B₁, C, and D. Consideration was given to the possibility of adopting standards for vitamins B₂ and E (many hold that insufficiency of vitamin B₂ gives rise to pellagra; vitamin E is necessary for successful reproduction in both male and female), but it was felt that our knowledge of the nature of these vitamins, and of the pathological results to which their absence gives rise, is still insufficient to justify the adoption of standards and units.

The standards for vitamins A and C, provisionally adopted in 1931, have been altered. Those chosen in 1931 were found to have certain defects which impaired their usefulness; the substitution of more clearly defined and more easily reproducible chemical substances is a useful step in advance. As vitamin A, pure β -carotene has been chosen in the place of the standard preparation of carotene recommended by the previous conference. The vitamin C standard chosen is ascorbic acid, a substance which the work of Szent-Györgyi (Hungary) showed to be identical with vitamin C. No change has been recommended in the case of the vitamin B₁ and D standards. The former has proved highly convenient in practice—of all the standards chosen by the 1931 conference the vitamin B₁ standard has perhaps proved most satis-

factory—and a large stock, sufficient to last for many years, is available at the central institution from which the standards are distributed—the National Institute for Medical Research, London. The vitamin D standard remains unaltered, with the proviso that it may be replaced when exhausted (or should it become for any reason unsatisfactory) by crystalline vitamin D in suitable solution. Large quantities of the standard solution of irradiated ergosterol are available.

The units remain the same in all cases. Where a change has been made in the standard material the old units have been restated in terms of the newly adopted substance. The desirability of leaving the original units unaltered is emphasized by the fact that certain of the units recommended by the 1931 conference have been adopted into the pharmacopoeias of a number of countries.

England and Wales

Honorary Degrees at Bristol

At a congregation on Saturday, June 30th, at the University of Bristol, honorary degrees were conferred upon Sir Robert Muir, M.D., F.R.S., of Glasgow, who had been selected to receive this distinction at the centenary of the University in 1933, but was unable to attend; upon Dr. Patrick Watson-Williams, an old student of the Bristol Medical School, who has distinguished himself as a pioneer in laryngology and rhinology; and upon Dr. George Parker, a learned medical historian who, after serving his full time as physician to the Bristol General Hospital, became honorary medical librarian to the University of Bristol. Dr. Parker has contributed a great deal to our knowledge of the methods of licensing medical practitioners in Great Britain, and his admirable marshalling of the chronicles of medical practice in Bristol is appropriately recognized by this honorary degree. He graduated with honours in the Moral Sciences and History Triposes at Cambridge in 1877, and now, more than fifty years later, he is once more eminent in these studies. In 1924 he was president of the Association of Physicians when it met at Bristol.

West London Medico-Chirurgical Society

The fifty-second annual dinner of the West London Medico-Chirurgical Society took place at the Trocadero Restaurant on July 4th, under the presidency of Mr. H. Tyrrell Gray. During the evening Sir Alfred Rice-Oxley handed to the president, who received them on behalf of the society, the presidential collar and the silver cup which have been subscribed in memory of a very old member, the late Dr. Rickard Lloyd. Lord Macmillan, in proposing the health of the hosts, remarked on the fact that the society was associated with the West London Hospital, and this gave him an opportunity for an appreciation of the service which the medical profession rendered to the voluntary hospitals—a service which was one of the profession's greatest achievements and honours. It was exemplified conspicuously in the work of the president, Mr. Tyrrell Gray, at the Hospital for Sick Children, of which the speaker happened to have some close knowledge. Lord Macmillan went on to refer to the death, announced that morning, of Sir James Kingston Fowler, and said that one of the most striking things about Fowler's great career was his endeavour in the ranks of the medical students of London to create the university spirit. That was a difficult thing to do in the days when Fowler laboured, because at that time the University of London was little more than an examining body, which could hardly be expected to evoke the same pride and affection as a university in the complete sense of the word.

Things had now changed, however, and would change yet more in the near future, with the rising on that magnificent site in Bloomsbury of a new centre of learning. Associated with it would be the new Post-Graduate School of Medicine at Hammersmith, which was within the area of the West London Society. He begged his medical friends to look with benevolence upon the ambitions of the University of London and to give its projects all support. Mr. Tyrrell Gray replied to the toast in a few happy sentences, in which he expressed his own personal indebtedness to his fellow officers and to the general body of members. Dr. F. J. McCann proposed the health of the guests, to which there were two replies, one from Sir F. Stanley Jackson, who described humorously some of the tribulations to which the chairman of the Selection Committee of the English team in the test matches is subject, and the other from Mr. V. Warren Low, president of the Royal Society of Medicine. As president of a society which can date itself back, though under another name, for 129 years, Mr. Low expressed a fatherly interest in the West London Society, founded fifty-two years ago by a few practitioners in that locality, and now a very prosperous body of 300 members, with a distinguished list of past-presidents.

Provision for Cases of Infectious Disease

The Ministry of Health has issued to local authorities in England and Wales copies of the Public Health (Treatment of Infectious Disease) Regulations, 1934, which came into operation on July 1st. In an accompanying circular it is explained that hitherto there has been no legal obligation on a local authority which has provided a hospital for the treatment of infectious disease under Section 131 of the Public Health Act, 1875, to receive into that hospital a person suffering from infectious disease who is not an inhabitant of the district. Nor is there any obligation on the authority to provide treatment for infectious disease, or to meet the cost of treatment otherwise provided, for an inhabitant of its district who is temporarily outside the district. There was thus no general legal provision which definitely placed the responsibility for the treatment of a person who is found to be suffering from infectious disease while outside the district of which he is an inhabitant, either on the authority of the district in which the disease is discovered or on that of the district of which he is an inhabitant. The primary public purpose of the hospital treatment of infectious disease is to prevent the spread of the disease; and as the population exposed to risk is that of the district in which the disease is discovered, it is generally recognized that the proper course is for the authority of that district, as the body responsible for preventing the spread of disease therein, to provide the necessary treatment. The Minister's attention has, however, been drawn to certain cases in which an authority disclaimed responsibility for the treatment of persons temporarily living in its district and sent them back to their homes, although it was not denied that hospital treatment was required. Such a course is detrimental to the public health, inasmuch as it delays the provision of treatment and involves risk of the spread of the disease. The new regulations accordingly provide that an authority shall have the same powers and duties in relation to the provision of hospitals or temporary places for persons who are for the time being within its district, and are suffering from infectious disease, as it has in respect of the inhabitants of its district. The regulations will not affect the right of an authority to decide, on the advice of its medical officer, what cases of infectious disease should be treated in hospital and what cases can satisfactorily be treated otherwise. Their object is to secure that the authority's decision should be based on

medical considerations alone, with a view to the most effective control of disease and the best use of the available accommodation. The regulations will not apply to hospital committees established under the Isolation Hospital Acts, 1893 and 1901; since the powers conferred by those Acts make no distinction between inhabitants of the hospital district and those persons temporarily resident in the district.

Birmingham Medical Reunion

The Faculty of Medicine of the University of Birmingham proposes to inaugurate the winter session of 1934 by holding a more extended series of meetings than hitherto, in order to allow of former members of the school being present at the various functions. Besides the usual address and the annual dinner of the school, a series of post-graduate lectures will be given at the affiliated hospitals. The preliminary programme for Thursday, October 4th, and Friday, October 5th, has now been sent to past students by the dean. On the first day there will be lectures at the Queen's Hospital in the morning and afternoon; and at 5 p.m., in the medical theatre of the University, Dr. F. Brett Young will distribute the prizes to students and give an address. At 7.45 p.m. a reception by the dean at the Grand Hotel will be followed by dinner in the Grosvenor Room. On Friday there will be lectures at the General Hospital, and at the Children's Hospital, Ladywood Road. Those who send notice of their intention to be present will receive a further communication and detailed programme during September.

Eichholz Memorial Clinic, London

The Prince of Wales opened, on July 6th, the Alfred Eichholz Memorial Clinic and Institute of Massage and Physiotherapy by the Blind, describing it as one of the most important additions to the National Institute for the Blind, and one of its biggest activities. The whole cost of equipping this clinic has been borne by Mr. W. Eichholz as a memorial to his cousin, the late Dr. Alfred Eichholz, formerly chief medical inspector of the Board of Education, and at the time of his death last year a member of the council of the National Institute. It is proposed to conduct its activities in connexion with the Institute's school for blind masseurs, and to serve the class of patient able to pay the usual fees for private treatment. The existing evening clinic will continue its work for hospital and other patients. The new establishment is situated at 206, Great Portland Street, where the whole of one large floor has been converted into a suite of cubicles, bathrooms, rest-rooms, and consultation rooms. The balneological section comprises foam, sulphur, pine, wax, brine, and shower baths. The electrical section contains some of the most modern developments in this line of therapy. Treatment will be given under medical supervision by blind persons who have qualified as chartered masseurs. The Prince commented on the undaunted perseverance and courage which had enabled the blind to make a livelihood, contribute to the social and economic life of the nation, and to excel in certain lines of work such as massage. In a survey of the work of the National Institute, Sir Beachcroft Towse, V.C., its chairman, stated that in addition to its weekly newspaper there were issued annually half a million volumes in Braille and Moon type; financial assistance was rendered to many other institutions which were catering for the needs of the blind. He pointed out that the new clinic, as well as being a treatment centre, would also serve as a clearing-house for all blind masseurs and masseuses. Lord Moynihan, proposing a vote of thanks to the Prince of Wales, spoke of the humility which those

with vision must feel when brought to realize how magnificently the blind had triumphed over the handicaps inflicted by the loss of sight. He noted with pride that these great qualities were a national possession.

Scotland

Health of Edinburgh

The annual report of Dr. John Guy, medical officer of health for the city of Edinburgh, states that the estimated population for the city is 452,773, an increase of 4,973 over that for the previous year. The birth rate was 15.1 per 1,000, the same as in 1918, the total number of births being 6,835. During the year there were 5,964 deaths, giving a rate of 13.2 per 1,000. The infantile mortality was the lowest yet recorded, being 66 deaths per 1,000 births. There was a slight increase in deaths from tuberculosis, the number being 322 as compared with 313 in the previous year. An arrangement between the Corporation and the University, whereby the latter conducts bacteriological services for the city, was continued, and among these was an investigation of fifty samples of milk supplied to the city. It was observed that the bacterial content varied from 20,000 bacteria to 154,000,000 per cubic centimetre; twenty samples showed between 1,000,000 and 3,000,000. There was found to be no relation between the outward appearance of the shops and the character of milk, for good samples were often obtained from small shops in the slums, while thoroughly bad samples were procured from pretentious and apparently clean dairies in the suburbs. The investigation revealed a necessity for investigating and improving, where necessary, methods of milk distribution. The report comments on the training of probationer nurses in the municipal hospitals; it had been difficult to provide probationers with sufficient surgical training, although the general training in such hospitals was particularly full. In the school medical service a system of class-room inspection was introduced in which the teacher and the doctor collaborated. In this way 25,000 children were inspected instead of 4,000 at the nine-year period as formerly.

Hospital for Crippled Children

At the annual meeting of the Princess Margaret Rose Hospital for Crippled Children at Fairmilehead, Edinburgh, with the Earl of Home presiding, the report was presented by Lady Findlay, and an address on the work of the hospital during the past year was given by Mr. W. A. Cochrane, F.R.C.S.Ed. Mr. Cochrane said that during the year eighty-four new cases had been admitted, while seventy-two patients had been discharged cured or greatly benefited by the treatment. There had been nine cases of congenital club-foot and nine of congenital dislocation of the hip-joint, which had been successfully treated by repeated manipulations and reapplication of plaster cases. There had been sixty-one operations, mainly of a major character, which had all been carried through successfully without any post-operative infection. The general conclusion reached in regard to crippled children was that 75 per cent., if attention was given sufficiently early, could be converted into useful and active citizens. Patients requiring orthopaedic treatment could be divided into two clearly defined classes—those who could not walk at all and those who walked imperfectly. Certain fundamental activities were necessary for a child's independent life: that he should be able to stand on his feet; that he should be able to get up and down out of a chair; and that he should be able to go

up and down stairs. It was only when the crippled child was able to do these three things that he became independent. The chief benefit to be obtained from the hospital was from the fully organized system of care which the hospital and its clinics provided. This gave prompt admission, the prolonged stay necessary for the treatment of cripples, and after-care by a clinic near the patient's own home where remedial exercises and other measures prevented relapse. This out-patient work was of the utmost value. It provided that early treatment at the first signs of crippling conditions which often obviated the necessity for operation later. During the past year the county authorities through the active support of their public health committees had given increasing assistance to these out-patient clinics. He hoped that before long all the areas which the hospital was designed to serve would have associated clinics for collecting patients and for their after-care. Lord Provost W. J. Thomson moved the adoption of the annual report, which showed that the expenditure for the year had amounted to £7,405; against this £3,366 had been received in patients' fees, leaving a deficit of £4,038. Covering this deficit £3,855 had been received in legacies, donations, etc., and a further sum of £1,000 from the Scottish Branch of the British Red Cross Society towards running expenses. Sir Thomas Whitson, commenting on the accounts, said it was unsatisfactory that this young institution should have to use legacies to secure its deficit; he hoped that local authorities in Edinburgh and other places would send more paying patients to what was a wonderful institution. The time had come, he said, when the co-ordination of the hospital organizations in the city was necessary, and he hoped that, as the result of such co-ordination, a large number of patients would be sent to the Fairmilehead Hospital.

Royal (Dick) Veterinary College

Professor Sir Thomas Hudson Beare, presiding at the annual prize-giving of the Royal (Dick) Veterinary College, Edinburgh, on July 2nd, stated that the affiliation of the College with the University of Edinburgh had passed through most of the stages and was now only waiting the approval of the King. In speaking of the report of the Committee on Cattle Diseases, he said that the general public did not realize what a great industry was involved in the production of milk, for in the year 1931 the value of this industry at the farms was £64,000,000, and this value was doubled by the time the milk reached the consumer. The committee had recommended that the veterinary service should be entrusted with the duty of carrying out periodical clinical examination of dairy herds with a view to the elimination of certain diseases. The Board of Governors was anxious to give assistance to students desirous of taking the diploma in veterinary State medicine, but was at present somewhat limited by the size of the buildings and staff. Very soon additional accommodation would be necessary, and the funds for this would require to be sought from the community as a whole, especially the farming community. Principal O. Charnock Bradley said that in the past two years the number of students in the College had been a record. He believed that the College kept fully abreast of the changes in veterinary science, and this was particularly noticeable in the department which dealt with diseases of poultry.

Edinburgh Hospital for Sick Children

At the annual meeting of the Royal Edinburgh Hospital for Sick Children Mr. Colin M. Black, who presided, said that the number of cases treated in the past year, though slightly below that for 1932, was still above 3,000; while out-patient attendances had reached nearly 44,000. The

directors were proceeding with the equipment of a biochemical laboratory, which would be in working order by autumn of the present year. The ordinary expenditure of the hospital and its convalescent home exceeded the income by over £5,000, but the deficit was met by legacies and special donations, which had amounted to £9,579. Professor John Fraser said it would be a matter for regret if the voluntary system of hospital support were abandoned. A hospital which it was certainly a duty to maintain on its present basis was the Edinburgh Hospital for Sick Children, for it was managed and organized in an ideal way. The institution had the unique privilege of caring for those whose future was still untold; to care for a sick child was not only a primitive instinct in man's nature, but was an urgent and sacred duty. The report of the hospital indicates that there was a very high incidence of acute rheumatic infection during 1933, since sixty-two new cases were admitted during the year in addition to a large number of old cases readmitted. The infection was connected with an epidemic of scarlet fever in Edinburgh during 1933, which was one of the largest that the city had experienced; this fact appears to be of particular interest in the light of recent investigations into the causes of both rheumatic infection and scarlet fever.

Ireland

King's Professorship of Medicine, T.C.D.

Dr. V. M. Synge has been elected to the King's professorship of the practice of medicine in the medical school of Trinity College, Dublin, to fill the vacancy caused by the death of Dr. F. C. Purser. Dr. Synge received his medical degrees in 1918 at Dublin University, and proceeded M.D. in 1919. He was elected a Fellow of the Royal College of Physicians of Ireland in 1921.

Irish Medical Association

Dr. R. J. Rowlette presided at the annual meeting of the Irish Medical Association, held on June 26th in the Royal College of Surgeons, Dublin, at which, for the first time in the history of the association, there was a scientific session. Dr. E. T. Freeman opened a discussion on the modern treatment of pulmonary tuberculosis. He said that with the return of normal conditions at the end of the war there came a reawakening of interest in many medical problems and a rapid diffusion of knowledge. This was most striking in tuberculosis, where the main advance had been along lines that were partially surgical. It had fostered the physician with the surgical bent, and in some cases had produced the complete specialist, who was both physician and surgeon. Mr. A. B. Clery discussed the operative treatment of tuberculous disease of the lungs, and described the condition under which surgical operations could be carried out with ease and safety to the patient. The operations, he said, should be followed by efficient sanatorium treatment. Mr. C. MacAuley, vice-president of the association, gave a demonstration of the thoracoscope. Dr. J. A. Harbison, medical officer of health for County Dublin, in the course of an address on the relations of the medical officers of health and general practitioners, said that although public health authorities were concerned chiefly with the prevention of disease, it was impracticable to draw lines of demarcation between treatment and prevention. If success was to be complete whole-hearted collaboration between the official and private practitioners of medicine had to be secured. The co-ordination of the special services set up by the State had been entrusted to the medical officer of health, for their creation had, in the main, been prompted by the tendency in preventive medicine to devote consideration

more to the individual than to his surroundings, to seek in the man himself rather than in his environment the causes of disease. As a sanitarian the medical officer of health must continue persistently to scrutinize the causes and sources of disease which were traceable to man's surroundings, but it was in the field of individual hygiene that the future would find most work for him. Dr. T. J. R. Maguire, County Roscommon, said that all school children whose parents desired it obtained free medical examination. If the free examination was to be followed, as a matter of course, by free treatment, then the profession would have just cause for complaint. If the sifting of patients into those who could afford private treatment and those who could not were neglected, then there would be a loss to the private practitioner. If, however, the sifting were effectively done the result would be a gain to the profession. In County Roscommon no children obtained treatment until their parents submitted a certificate that they could not afford treatment privately. He said that the whole-hearted manner in which the profession co-operated in public health schemes was unique; no other guild or craft laboured so assiduously for its own extinction. Dr. T. P. MacDonnell considered that the present tendency was for new health schemes to encroach on the work of the general practitioner. While the latter was more than ever anxious to carry on the tradition, it had to be realized that the sources of remuneration which had existed heretofore had in many instances disappeared. Dr. T. F. Armstrong said that the health services of Ireland had been taken from countries where conditions were totally different, and were not yet on a sound foundation. He suggested that the county medical officers of health should standardize their methods. Dr. J. A. Musgrave, medical officer of health for County Louth, also read a very interesting paper on public health administration.

In the afternoon the business meeting was held. Dr. Rowlette thanked the members for his re-election, and said that by giving him a third year of office they had conferred on him an honour unique in the history of the Irish Medical Association. He was glad to say that the General Council of Medical Associations, recently formed, had been active, and that all representations to Government Departments were now made by this body, which could speak with unquestionable authority. Professor T. G. Moorhead, President of the British Medical Association, was elected an honorary member of the I.M.A.

Armagh Mental Hospital

The annual report of the Armagh Mental Hospital states that on December 31st, 1933, there were 562 patients—289 males and 273 females. The admissions throughout the year numbered seventy-four; the total cases being 638, or thirteen more than in 1932. Discharges numbered twenty-nine; twenty-five of these were patients who had recovered. There were thirty-four deaths. The daily average number of patients under care was 563. Thirty-seven males and thirty-two females were admitted under reception orders. One male voluntary patient was admitted, and four females were admitted under transfer. Among the admissions were children of 2, 8, and 13 years, and a patient of 23. These were imbeciles, and could be improved but not recover. Six patients were over 70, a fact which would also tend to lower the recovery list. The ratio of recoveries to admissions was: males, 40.5 per cent.; females, 27.7 per cent. There had been an unusual amount of sickness during the year; an epidemic of influenza attacked sixty-six patients and five of the staff. There was also typhoid fever among both staff and patients, the disease being fatal in the case of one attendant and two patients. There was a slight increase in the number of paying patients.

Reports of Societies

CLINICAL PATHOLOGY OF COMA

The summer meeting of the Association of Clinical Pathologists, held at the Royal Infirmary, Gloucester, on June 23rd, with Dr. E. N. DAVEY, pathologist to the hospital, in the chair, was devoted largely to a consideration of the clinical pathology of coma.

THE BARBITURATES

Dr. G. ROCHE LYNCH, speaking on the toxicology of the barbiturate drugs, said that all drugs of this group had the common basis of a combination of malonic acid with urea, the different proprietary preparations being produced by the substitution of various radicals at varying points. Some of these preparations, in addition to the malonylureide compound, also contained various proportions of amidopyrine or pyramidon. A single pharmacological dose produced sleep; repeated doses might, in sensitive persons, give rise to such symptoms as drowsiness, ataxic gait, ptosis, diplopia, and visual hallucinations. The barbiturates were not cumulative in the ordinary sense of the word, but after prolonged administration the effects might be slow in disappearing. The margin between the effective and the toxic dose was small. After a toxic dose symptoms might appear in a few minutes: these were headache, ataxia, vertigo, and drowsiness passing on to coma; there might be a preliminary period of excitement. On the establishment of coma the plantar reflex might become Babinski in type and the breathing periodic; the pupils were small but not pin-point, and the temperature became subnormal: bronchopneumonia tended to appear after the first twenty-four hours of coma. Dr. Lynch pointed out that many persons had an idiosyncrasy to the barbiturates, and said that these should be used with caution in toxic conditions of the liver, hyperthyroidism, chronic sepsis, renal disorders, and in all states of allergy. There was considerable variation between the minimum and the average fatal dose: for veronal the former was 15 grains and the latter 50; for luminal, 15 and 30 grains. Post-mortem findings were not characteristic: bronchopneumonia was almost constant, but of no special type; the liver and kidneys underwent fatty and parenchymatous change, but this might be evident only on microscopical examination. Dr. W. D. Newcombe had pointed out to him that the cerebellum frequently showed a pressure cone. Pemphigoid and bullous rashes might appear on the skin. Dr. Lynch questioned whether in all cases returned as suicide from barbiturate poisoning the drug had actually been taken with fatal intent. In one case ten tablets of a barbiturate preparation had been taken during one night: on recovering consciousness the patient recollected having taken two only; the remaining eight had apparently been taken in a state of somnambulism induced by the drug. When patients were given more than sufficient tablets for one night they should be instructed to take the night's dose and then to place the remainder in an inaccessible spot.

In the treatment of barbiturate poisoning the stomach should be washed out; for this purpose alkali should on no account be employed, as it rendered the poison more soluble; strong coffee and glucose should be left in the stomach, and the wash-out repeated two or three times, at intervals of four hours or so. Colonic lavage was useful, and should be repeated after twelve hours. Cardiac stimulants should be given in full doses. Lumbar or cisternal puncture was of the utmost importance, and should be repeated every twelve to fifteen hours, so long as the case seemed to demand it. This procedure served both to remove the poison, which was excreted in high percentage into the cerebro-spinal fluid, and to relieve cerebral pressure. Other methods of treatment included strychnine, picrotoxine, and alcohol. Great claims had been made for treatment with strychnine, and massive doses had been given. Although strychnine was valuable reasonable caution should be exercised in its use. In identifying a case of barbiturate poisoning the urine, stomach

contents, and cerebro-spinal fluid should be examined for the poison: examination of the cerebro-spinal fluid was of particular importance, as drainage should be persisted with until the drug had practically disappeared. Dr. Lynch described the methods of identification of barbiturates in the various body fluids, and pointed out that they fell into two groups, one of which was rapidly broken down, while the other was more stable. Dial belonged to the former, and the amount of this excreted in the urine might be very small. Dr. J. G. GREENFIELD said that he had found protein in the cerebro-spinal fluid. In view of the evidence that cerebral oedema, with increase of cerebral pressure, played some part in the production of symptoms he questioned the safety of cisternal puncture.

CEREBRAL CONDITIONS

Dr. J. G. GREENFIELD gave an account of several cases of subdural haematoma. This condition appeared to be becoming more frequent, probably on account of the increase in motor accidents. It was much commoner in males than in females. The cerebro-spinal fluid might be absolutely normal and not even under pressure; sometimes it showed slight discoloration of the supernatant fluid after centrifugalization and an increase of protein, but these features were not constant. Flakes of fibrin might be present in the fluid as withdrawn; their presence constituted an important diagnostic aid. It was difficult to account for the long latent period between injury and the onset of pressure symptoms on the assumption of actual continuance of the haemorrhage. The increased cerebral pressure might be brought about by imbibition of fluid into the haematoma, this being occasioned by increase in the osmotic tension of the haematoma contents, the result of breaking down of the blood.

Dr. A. G. SHERA (Eastbourne), describing several cases of coma due to subarachnoid haemorrhage, drew attention to the existence of a spinal as well as a cerebral type: the former never produced coma, and the main symptom was severe pain in the back, which was relieved by lumbar puncture. In both forms the cerebro-spinal fluid was almost invariably blood-stained, the blood being intimately and uniformly mixed with the fluid: on centrifugalization the supernatant fluid was coloured to a degree depending on the distance of the date of the haemorrhage. Besides giving relief to the headache lumbar puncture was an important diagnostic measure; the condition was usually accompanied by some degree of fever, and, short of examination of the cerebro-spinal fluid, the diagnosis between it and meningitis might be impossible. Massive albuminuria might occur, and papilloedema and retinal haemorrhages were common. Dr. Greenfield demonstrated microphotographs illustrating that deficiency of the media of the cerebral vessels was common at points of bifurcation; it was at these deficient sites that the aneurysms formed, whose rupture gave rise to subarachnoid bleeding.

Dr. S. C. DYKE reported seven cases illustrating the occurrence of coma, and in some cases convulsions and other grave cerebral manifestations, in association with raised blood pressure. He used the term "hypertensive encephalopathy," first employed by Oppenheimer and Fishberg, to describe the condition. Five of the patients were children or young adults; in addition to coma they all had convulsions, and some of them amaurosis. In the two elderly patients convulsions were absent. The younger patients were suffering from acute glomerulonephritis; there was no evidence of renal damage in the two older subjects. The feature common to all was a raised blood pressure. Dr. Dyke pointed out that when associated with renal damage hypertensive encephalopathy was usually described as uraemia; in none of his cases, however, was the blood urea significantly raised, and the term was therefore not applicable. Treatment was by venesection, lumbar puncture, and magnesium sulphate rectally and by mouth: all the patients made a good recovery. Dr. CUTHBERT DUKES considered that in all the cases described the manifestations might properly be called uraemic. Dr. A. F. S. SLADDEN (Swansea) suggested that in the light of present knowledge some examination into the meaning of the term "uraemia" was advisable.

SEX: ITS NATURE AND ABNORMALITIES

The Section of Obstetrics and Gynaecology of the Royal Society of Medicine joined with the Medico-Legal Society, on July 6th, for a discussion on "Sex: its Nature and Abnormalities, considered from Biological and Legal Points of View." Professor W. BLAIR-BELL, president of the Section, was in the chair.

BIOLOGICAL ASPECTS OF SEX

Professor F. A. E. CREW, of the department of animal genetics, University of Edinburgh, said that when an understanding was sought of the attributes of man and the complexities of society it was customary to begin with a comparative survey of similar phenomena in other forms of life. The politician, the cleric, the devotee, commonly asked for the biologist's endorsement that what he held was right or more than right, even natural. But human society was quite a unique biological phenomenon; it was doubtful whether there was anything like it among the experimental material of the biologist. In that material there were social groups, but no morals; crime, no doubt, but not sin. The reference to the lily or the ant might be useful to the philosopher, but the student of human behaviour could hardly hope to find an explanation of many things that puzzled him by turning to the rabbit or the bird. The biologist was no longer concerned with the search for an understanding of the nature of sex itself; he contented himself in this stage of the development of his science with a discussion and analysis of those differences which prompted him to regard one individual with one particular kind of organization as a male and another of a contrasted kind as a female. The more one knew of sexual differences the less one knew of sex itself. Sex would seem to imply differences of structure and behaviour of two dissimilar individuals and of two reproductive cells—sperm and ovum—in the mating of the individuals. Because the mating of two dissimilar individuals of the species commonly resulted in conception, nothing was easier than to conclude that the nature and meaning of sex could only be considered and recognized by bringing it into essential relation with reproduction. Thus the notion of a purpose in sex was revealed, the service of the race; but that was not a contribution of biology, it was an imposition on that science.

The biologist knew that sexuality and reproduction, though commonly related, were, in certain forms of life, not only separately distinguishable but even completely dissociated. Reproduction without sex was just as common as reproduction with sex, and sexual reproduction, though very different from asexual, could claim no marked advantage from the biologist's point of view. It was, however, a fact that in an ever-increasing number of species the existence of sex chromosomes was being demonstrated, and it was shown that in a considerable number of cases there was dissimilarity between the sexes in sex-chromosome constitution. Abnormalities in the distribution of sex chromosomes were always associated with the sex characterization of the individual. In the fruit-fly, *Drosophila melanogaster*, it was by no means uncommon (occurring in 1 in 200 cases) to find all the characters on one side of the body male and all those on the other female. In this insect it was possible to get a graded series of abnormal sex types, from the super-female, in which the female characters were greatly exaggerated, to the super-male; and associated with each type there was a constant abnormality in the relative number of X-chromosomes and autosomes. He instanced also the gipsy moth, *Lymantria dispar*, where the male and female determining influences were such that, crossing Japanese males with European females, half the resulting males, though looking and behaving like males, were, with reference to their sex-chromosome constitution, females. What, therefore, was a male, and what a female, when it was possible to produce any desired grade of intersexuality? Again, there was the marine worm, *Bonellia*, whose sexual destiny was determined by the place where the larva, sinking in the sea, touched bottom. If it alighted on or near the proboscis of a female it became a male; if well away from the female, then it became a

female. What was male and what was female? The biologist, if honest, would say that he had no opinion. He could identify a male and a female, but in the presence of the intersexual form he had nothing to say.

MECHANISMS WHICH DETERMINE SEX BEHAVIOUR

Dr. B. P. WIESNER, continuing the biological argument, said that in the male rat sex activity was comparatively simple. It would attempt to mate with any other animal of its kind of similar appearance, whether male or female. The distinction between the sexes which resulted in normal or heterosexuality appeared to be definitely a secondary phenomenon in evolution. Mating was actually restricted to union between male and female, not, however, because the first male selected, but because the second male did not permit. The testes could be removed from the rat after puberty without interfering for a considerable time with the sex life of the animal, whereas complete removal of the anterior lobe of the pituitary resulted in immediate disappearance of all sex activity. Such activity was determined by some as yet unknown substance such as was extracted from the anterior lobe. Sex activity in animals varied, first, with regard to its intensity—it could be prolonged and vigorous, or intermittent and sluggish—and secondly, with regard to its structure and the integration of the various movements which constituted in their totality the sex act. Intensity and structure were independent of each other, or had very slight correlation. After hypophysectomy it was possible to restore completely spontaneous activity without restoring sex activity. Therefore it was assumed that there was a group of substances which canalized energy into sexual channels, and a second factor, or perhaps many factors, which produced the energy itself. It was also worth noting that associated with the factors which determined sex behaviour were factors which determined certain specific, but not easily described or measured, activities of the animal. For example, rats which were wild or brutal would lose those traits in a few days after complete removal of the anterior lobe. Many of the factors responsible for highly dynamic motivation were associated, if not identical, with the factors responsible for sex behaviour. Maternal behaviour in the rat and other animals was a complex thing, but again it was, to some extent, activated by chemical factors belonging to the hypophyseal ovarian mechanism. Homosexuality in rats could be artificially produced by keeping males together for a certain length of time.

INTERSEXUALITY IN MAN

Dr. H. GARDINER-HILL said that intersexuality was only occasionally met with in medical practice. The study of the subject included various types of hermaphroditism and sex reversal. The underlying pathology was very little understood. As a physician his thoughts naturally turned to the endocrine aspects of these problems. Professor Crew, in his biological survey, had pointed out that there were other and probably more important aspects. The initial bias in sex differentiation seemed to begin with the hereditary and chromosomal factor, presumably modified afterwards by other influences, endocrine and environmental. With regard to the endocrines, it was now generally accepted that the hormonal stimulus which led to the growth of the accessory sexual organs and the secondary sex characters came from the gonads themselves. The pituitary was also concerned in sex development, but did not seem to play any part in sex differentiation. In clinical work destructive lesions of the pituitary in children were associated with infantilism. The renal cortex provided another endocrine influence. Precise information as to the function of this gland in this connexion was lacking, but cortical tumours were found associated with varying degrees of virilism in the female, and so it was assumed that a hormone was produced which had a masculinizing influence. Such was a brief outline of the main endocrine influences which played a part in the development of sex. With regard to clinical aspects, the grades of intersexuality found in man included true hermaphroditism, combining in one individual the bodily characters and generative cells of both sexes—a rare condition, though the president of that meeting,

Professor Blair-Bell, had reported on one very interesting case of a girl of 17, who had commenced life and passed puberty as a normal girl, and menstruation had ceased after eighteen months and masculine characters appeared. Pseudo-hermaphroditism was more common where genital ducts were found in contrast with the gonads. A third group of abnormal conditions must be referred to under the heading of the adrenogenital syndrome. The pathological lesion might be either diffuse cortical hyperplasia or a neoplasm, which might be either benign or malignant. The influence of such a lesion might manifest itself in different ways, depending on the age of the individual at onset and also the type of lesion. Successful operative removal of cortical tumours had been reported in several instances. The gross condition was rare in comparison with the very large number of individuals who showed signs of minor disturbances in the sexual sphere, such as, in the female, slight hypertrichosis of the male type, poor development of the breasts, and so forth. In these individuals the condition did not seem to be serious or progressive, and there was seldom any evidence of an endocrine lesion, but, of course, the opportunities for pathological investigation were few and far between. One suspected that the abnormality was largely due to inherited influences, and other members of the family would usually be found to show the same tendencies.

MEDICO-LEGAL IMPLICATIONS OF MASOCHISM

Sir BERNARD SPILSBURY dealt with the problem presented by cases of masochism which had led to the accidental death of the individual during the act. Masochism was a condition in which a person subjected himself to severe physical restraint, discomfort, or even pain, with the object of obtaining sexual gratification. One of the difficulties from the medico-legal point of view was that the rite was usually practised in secret, and in fatal cases there might be no clue in the history of the individual to explain the conditions under which death came about, so that there was a risk of the fatalities being interpreted as suicide or even murder. His own experience concerned three individuals—two of them lads, and the other a man of 34—who had tied themselves up so completely that the binding might have been thought the work of another person, and only by careful analysis was it shown to have been the act of the individual himself. The cause of death in each case was asphyxial suffocation, hanging, or strangulation. Whether an attempted asphyxia was the chief danger in this practice could not be stated. He believed that many of the cases found in coroners' courts as suicide, otherwise inexplicable and occurring in young individuals, should properly have been interpreted as accidental deaths due to masochistic practices. Possibly some cases of suspected murder might come into the same category. It was an interesting and important legal problem in connexion with sex abnormality.

THE ENDOCRINES IN SEX CONSTITUTION

Professor W. BLAIR-BELL said that it was well known that in the human embryo it was impossible, until about the eighth week, to say whether the genital organ was going to be a male or female gonad. About the eighth or ninth week determination in one direction or another occurred, but subsequently to that period there must be a large extent bisexuality. He thought a mistake had been made in describing the primary sex factors as being merely those of the constitution of the gonad itself. Quite clearly, if the development of the gonad was doubtful for a space of time it might be converted into either the ovary or testicle, or, in very rare cases, both might develop. He had always thought that the endocrine organs ought to be considered in this connexion, especially the supra-renal cortex, the anterior pituitary, and, possibly, the thyroid gland and the pineal gland. In connexion with hermaphroditism, he believed it was Bond of Leicester who reported a pheasant which was cock on one side and hen on the other. How was it such a thing happened? He laid down three aphorisms with regard to pseudo-hermaphroditism: (1) the secondary sex characteristics were opposite in nature to the anatomical structure of the gonad; (2) in pseudo-hermaphrodites it was always found

that secondary sex characteristics of the female were more perfect than those of the male—that is to say, a woman with testes might have most perfect secondary female characteristics; (3) in pseudo-hermaphrodites the ovaries were always much more fully developed than were the testes in pseudo-hermaphrodites of the opposite character. In a pseudo-hermaphrodite with testes, but with perfect female secondary characteristics the mind was that of a woman—indeed, generally very much of a woman. Therefore he thought the law was wrong in cases of nullity when it said that a person was male or female in accordance with the nature of the gonad. The gonads were not the only arbiters of sex.

Dr. LEONARD F. BROWNE said that Sir Bernard Spilsbury's cases of masochism were of special interest to those concerned with the treatment, on psychological lines, of sexual perversion and aberration. The condition of masochism had a very large variety of expressions, most of them, fortunately, not entailing fatal risks. There was also the opposite condition of sadism, where the individual desired, instead of suffering pain, to inflict it on others. Dr. MARGARET LOWENFELD said that among neurotic children the desire to tie themselves up was relatively common in prepuberal life. From a study of these children the habit did not appear necessarily to have reference to a post-puberal sexual impulse, although very possibly it was the oncoming of the post-puberal impulse which so exaggerated an already existing trait that it became dangerous to the individual.

Mr. L. R. BROSTER said that the appearance of secondary male sexual characters in the female had been associated with changes in the adrenal cortex. At operation on some sixteen cases it had been found in them all that the cells of the adrenal cortex were a bright pink—a stain which was not present in the normal individual. In these cases of virilism there was therefore a change in the cells of the adrenal cortex, and the change had also been found in the anterior lobe of the cortex. From the tenth to the seventeenth week of foetal life every female should pass through a male phase. There seemed to be a male hormone in the adrenal cortex which gave rise to male characters, and one could argue that with a very prolonged male phase in the female foetus that hormone might become converted and explain some of the occurrences of pseudo-hermaphroditism.

Professor CREW, who described the male as "nothing more than an 'improved' female," remarked that there was a chemical affinity between the male and female sex hormones; therefore might it not be that in the cases of virilism, whatever the factor was, it operated upon that chemical mechanism, transforming in some way or other the female sex hormone into the male?

Sir BERNARD SPILSBURY said that he could recall making a post-mortem examination on the case of a young man who had died in his bath from congenital heart disease. He was known to be abnormally developed, although he had all the secondary sexual characteristics of a man. The external sex organs, however, were found to be much more like those of a woman, but showed some intermediate characters, and internally there were male and female sex organs, both poorly developed. Asked whether he had discovered any cases of masochism in the female, he said that his experience had been only of fatalities, and these had all been in males. He thought it very unlikely that it was met with in the female sex. The practice might well originate in the prepuberal period, for amusement or by chance, becoming of greater significance on the individual's reaching sexual life.

The Far Eastern Association of Tropical Medicine will hold its ninth congress at Nanking, from October 1st to 7th, under the patronage of the National Government of China, and the presidency of Dr. J. Heng Liu, director of the National Health Administration and Central Field Health Station at Nanking. Scientific sections will meet on four mornings and two evenings. At the end of the conference there will be a choice of three tours—namely, to Peiping by railway, to Hankow by river, and to Hangchow by road. Inquiries should be sent to Dr. P. Z. King, National Health Administration, Nanking, China.

CORRESPONDENCE

Thyroid Addiction

SIR,—I read with much interest Dr. S. W. Patterson's article on thyroid addiction in your issue of July 7th (p. 6), and hope that it will once again call the attention of medical men to the dangers arising from the prolonged use of thyroid extracts.

In the *Journal* of March 14th, 1931, I published a short paper entitled "Unilateral Exophthalmos following Administration of Thyroid Extract," and at the end of the article I suggested that some restriction should be placed on the sale of thyroid products. I added that

"any physician of experience must have met with many cases in which long-standing ill-health with hyperthyroid symptoms has been caused by excess of this drug, and also certain acute cases in which sudden palpitation, giddiness, dyspnoea, and nervous terror have been brought about by prolonged overdosage."

Further, I stated that "in most cases the fault lies not with the physician but with the patient." In writing this I had in my mind two cases of thyroid addiction, one of whom is still under my care.

In my opinion thyroid extract should only be obtainable on a doctor's prescription, and the prescription should only be repeated for a limited period unless re-initialled by the prescriber. Möller, writing on the same subject in the *Acta Medica Scandinavica*, goes so far as to suggest that thyroid extract should be placed on the list of dangerous drugs.—I am, etc.,

Dublin, July 7th.

T. GILLMAN MOORHEAD.

Preliminary Ligature in Toxic Goitre

SIR,—The statement referring to ligature of arteries in toxic goitre, in the letter by Dr. L. Cunningham and Mr. Philip Hawe, published in your issue of June 30th, is contrary to my experience. Owing to the importance of the increase in the death rate recorded in the last report of the Registrar-General—namely, from 587 in 1921 to 1,404 in 1932—I had proposed, in the near future, to discuss the complications arising in the course of toxic goitre as well as the management of severe cases without complications, and the question of ligature of arteries would have arisen naturally. But, because of the position occupied by the two signatories to the letter referred to, and the importance that will be attached to their views, I feel that I should state now that I differ emphatically from the opinion they express. There are some who will remember that I expressed this view myself many years ago, but my experience in the intervening years has induced me to change this opinion.

My opinion in the earlier years was held because I had seen ligation carried out in a manner that was certainly liable to upset the patient. Many patients are seen who are extremely ill, and the number who are so ill does not decrease. In dealing with them every factor that makes for safety must be employed. Certainly many of these patients, even with the most capable preparation, would not stand the removal of a lobe with safety. Ligation of arteries has repeatedly changed an unsafe risk into a reasonably safe operative risk. I have seen it result in a gain of 14 lb. in weight in a few weeks, in a patient who had lost weight continuously while in hospital over a period of two months. Her weight at the time of ligation was 4 st. 1 lb., her normal weight being 8 st. 7 lb.

The technique of ligature must be carried out accurately and carefully, the artery being displayed without unnecessary trauma. It has been written that if the artery is not easily found the upper pole should be encircled with a ligature. A description such as this does not belong to the present period of thyroid surgery.—I am, etc.,

London, W.1, July 9th.

T. P. DUNHILL.

SIR,—I am grateful to Dr. L. Cunningham and Mr. Philip Hawe for expressing in your issue of June 30th (p. 1187) their concurrence with my views as to the use of avertin for toxic goitre operations. They make, however, a statement with regard to preliminary ligature of the thyroid arteries which I think calls for comment—namely, "In our experience in bad cases it is not helpful and in mild cases it is unnecessary, and we consider it too liable to upset the patient to justify its use."

The fact that preliminary ligature is unnecessary in mild cases seems to me to be so obvious as not to need stating. That it is not helpful in bad cases is entirely contrary to my experience, and I am not alone in believing the operation to be of value. I cited more than one instance in my article on the use of avertin, and actually preliminary ligature was done for eight of the 220 patients, on almost every occasion with obvious benefit. In most cases the operation was performed under avertin, in one under local analgesia. In some the disturbance to the patients was severe because they were so extremely ill, and one actually died; any other operation would have resulted in several more deaths. In others the disturbance was very slight, and in all (except the one mentioned) the operation served to convert a very bad "surgical risk" into a reasonable one. That the effect of artery ligature is only temporary I fully recognize, but I am convinced by experience that it is a measure of the greatest value in a few selected patients.—I am, etc.,

London, July 6th.

GEOFFREY KEYNES.

Operation for Toxic Goitre

SIR,—In a letter published in the *Journal* of June 30th (p. 1187) Dr. L. Cunningham and Mr. P. Hawe write of operating for toxic goitre after obtaining permission from the relatives while the patient herself is unaware that an operation "in the immediate future is contemplated." It is not clear from this whether or not their patients' consent is also given.

I believe it is illegal to operate without permission from the patient (unless she be under 21 years of age, or certified insane) though she need not know when it will take place nor when she is being anaesthetized. Some very nervous patients with toxic goitre repeatedly refuse operation until they are too ill to stand it and die in a thyrotoxic crisis. In such cases the fatal result could be avoided, I think, if the consent of the relatives only were necessary before performing thyroidectomy.—I am, etc.,

Bournemouth, July 3rd.

HAROLD COOKSON.

Pyloric Stenosis

SIR,—I have read with great surprise that in the pyloric stenosis of infancy the finding or not of the tumour is not of any particular importance. In July, 1930, in a special number of the *Practitioner* on diseases of children, I contributed an article on pyloric stenosis, a subject to which I had given ten years of special study in order to determine the value of the pyloric tumour, as a sign of the condition. My experience was then based on 100 consecutive cases, and I can say now that it is based on something nearer 200 cases. I found the tumour in practically 100 per cent. of the hospital cases; but what was of more importance, I not only found it myself but was able to demonstrate and convince skilled doctors not only at the Hospital for Sick Children, Great Ormond Street, but from all over the world, of its presence, and, further, all the 100 cases were operated upon and the presence of the tumour proved by the surgeon.

I don't deny that it may require both patience and care, but to hold that it is not the most important sign of the developed condition I venture to maintain would be a dangerous error.—I am, etc.,

London, W.1, July 7th.

F. JOHN POYNTON.

Sunbathing and Tuberculosis

SIR,—The article on sunbathing and tuberculosis by Drs. A. H. Gosse and G. S. Erwin, in your issue of July 7th (p. 15), raises a point of very great importance, for, although one would expect these facts to be realized by all medical practitioners, strangely this does not appear to be so; while among the general public the fallacy of the good effect of the direct action of the sun's rays is almost an obsession. It cannot be too much stressed that the proportion of cases infected with tuberculosis is very much larger than those known, or who know themselves, to have the disease; especially this so among "contact" cases, who may indeed especially endeavour to avoid the fell disease of which they have first-hand knowledge by a good dose of the sun. These evil results are found not only in tuberculosis but after any infection, and it is not uncommon to see a fresh attack of pneumonia occurring from too much sun in a patient convalescent of this disease.

It is well recognized at all sanatoria that not only an acute flare-up of the parenchymal disease, but even military tuberculosis, may occur after indiscriminate exposure, and the patients are cautioned of this. All those in touch with hospital, and especially dispensary, work will agree as to the large number of cases of acute activation of disease in both known and "new" cases as a result of the summer of last year, and the same state of things is occurring this summer. It should be a matter of routine with every doctor who is in charge of cases of tuberculosis repeatedly to warn the patient and also his contacts of the necessity of care in this respect. The intelligent interest taken by the public in living healthily has had its effect in decreased illness, especially among the young people; popular health journals have advertised the benefit accruing from Alpine sunlight treatment, but the technique and care which is necessary to its advantageous use is little stressed. The same applies to artificial sunlight treatment by the indiscriminate use of these lamps without supervision—I have seen several quiescent cases badly activated.

One has assumed that the effect of the sunlight is to liberate a flood of toxins which diminishes the resistance of the patient to the specific organisms with which he is infected, and that the effect of graduated light is much the same as graduated exercise in cases of chronic infection.—I am, etc.,

London, W.1, July 6th.

A. J. SCOTT PINCHIN.

Tuberculin

SIR,—I think I must be voicing the opinions of a good many general practitioners who, like myself, have used tuberculin over a period of twenty years in the treatment of pulmonary tuberculosis when I say that the expressed opinion of Dr. N. D. Bardswell (*British Medical Journal*, June 30th, p. 1136) on tuberculin fills us with amazement. That other methods of cure are preferred by the experts is perhaps true, but there is among general practitioners a vast amount of clinical evidence, more than sufficient to justify a direct contradiction to the statement that tuberculin is not seriously considered as a "cure."—I am, etc.,

Tonbridge, July 5th.

G. L. BUNTING.

SIR,—More than twenty years ago Dr. Noel Bardswell, after a perfunctory investigation upon the value of tuberculin AF (which is merely one of many forms of tuberculin, containing as it does chiefly exotoxins), condemned tuberculin as a whole, upon evidence which I knew to be quite worthless and misleading (see *Practitioner*, 1913). Somewhat later Dr. Halliday Sutherland, in ignorance which he now honestly deplores, attacked me for my views upon the value of tuberculin in diagnosis and treatment; but more knowledge and personal experience converted him to the views I have consistently held, practised, and preached for more than forty years. Dr. Sutherland candidly admitted so much at the Centenary Meeting of the British Medical Association.

It is sad that Dr. Bardswell, who can influence the L.C.C. in its policy concerning the greatest and most difficult medical problem affecting the life and health of the poorest sections of humanity forced to live in the greatest city in the world—London—dares to tell the lay public that tuberculin, as a means of diagnosis, as a remedy, and as an invaluable agent even in prognosis, is merely bunkum. As a pupil, friend, and faithful disciple of Robert Koch, I challenge the views of Dr. Bardswell. Statistics, based not upon post-mortem examinations but upon casual death certificates signed mostly by general practitioners, are certainly not above criticism in the elaboration of mortality statistics.

As the problem of tuberculosis is the greatest and most difficult problem in medical science, may I earnestly ask that a Royal Commission be appointed by the Government to collect evidence and call witnesses, so that the whole truth may be revealed upon the nature of tuberculosis and the best method of attacking the disease, so as to reduce the high mortality and morbidity constantly occurring in our midst, especially in our great cities?—I am, etc.,

W. CAMAC WILKINSON, M.D., F.R.C.P.
London, W.1, July 1st.

Bile Salts for Empyema

SIR,—Dr. H. R. Donald, in his letter in the *Journal* of June 30th (p. 1189), stated that it is possible to inject 10 c.cm. of 10 per cent. desoxycholate into the ear vein of a rabbit without harmful complications, though he qualifies his statement by adding that it is quoted from memory. I myself, however, know that less than one-third of this dose, dissolved in normal saline and administered in a similar manner, kills a rabbit within thirty seconds. I think, therefore, that the caution expressed in the article by Mr. B. R. Sworn and myself regarding the toxicity of this substance is justified.—I am, etc.,

Stafford, July 4th.

T. V. COOPER.

The Cancer Problem

SIR,—The review by Dr. J. A. Murray, in the *Journal* of June 16th, of Dr. A. T. Todd's recent paper on the selenide treatment of cancer is of very great interest, as, after explaining some of the many difficulties which have to be surmounted before we can solve the problem of malignant growths, it indicates one line of attack which has been to some extent successful.

After briefly reviewing the method of treatment by sulphur selenium colloid, radio-active selenium colloid, and deep x rays, Dr. Murray gives it as his opinion that the improvement brought about in a substantial percentage

of the cases treated was probably due, not to a direct attack on the cancer cells, but to gradual and systematic stimulation of the connective tissue stroma, leading to an encapsulation of the parenchyma cells, and eventual squeezing out of them in the manner which is found to have taken place in old scirrhous carcinomata. He states that "this encapsulation is essentially a non-specific overgrowth of the stroma, and it may be brought about in a variety of ways."

From the general trend of his review I infer that up to now no satisfactory method has been discovered for the eradication of malignant growths by way of a direct attack on the actual cancer cells themselves, and in inoperable cases we can only hope for success (a) if the degree of malignancy is comparatively slight, and (b) if we can succeed in stimulating the surrounding stroma to increased proliferation.

Dr. Murray gives us an idea of some of the great difficulties which have to be surmounted when he mentions that "even in the filterable tumours of the fowl, in which the evidence for the participation of a causative virus is strongest, the virus is so firmly combined with the cell structures that even the strongest viricidal antisera (active against filtrates) are incapable of rupturing the combination and of robbing living cell-suspensions of their property of giving rise to new growths." This, I take it, means that once the complex organic radical or group of radicals which constitutes the virus in question becomes joined up with a corresponding group in the living cell, it is almost impossible to dis sever them, and it would also seem that this virus remains henceforth as a permanent constituent, not only of that cell, but of all cells arising from it afterwards.

If this view is correct we must presume that once a cell becomes malignant the complex cell entity constituted of virus radical in combination with cell radical is capable of indefinite growth within the cell in the same manner as are all the other cell constituents, such as chromosomes, genes, etc., otherwise it would soon be eliminated by dilution.

Sir Frederick Gowland Hopkins, in his presidential address at the Leicester meeting of the British Association, stated that "a molecule within the system of a cell may remain in an inactive state and enter into no reactions until at one such surface it comes in contact with an enzymic structure which displays certain adjustments to its own structure. While in such association, the inactive molecule becomes (to use a current term) 'activated,' and then enters on some definite path of change." Sir Frederick, further on in the same address, when dealing with cancers which have arisen as the result of the prolonged action of certain tar constituents, mentions: "This structure, like that of the sterols, is one of condensed rings, the essential difference being that (in chemical language) the sterol rings are hydrogenated, whereas those in the cancer-producing molecule are not. *Hydrogenation indeed destroys the activity of the latter.*" The italics are mine.

Now, Sir, although I do not for a moment desire to minimize the great importance of the flanking encircling attack on cancer in the shape of stimulating the stroma tissue to increased growth, yet I cannot help thinking that in inoperable cases at least no satisfactory method of treatment will be discovered which will suit every class of case until we find some means of directly attacking the cancer cells. I fully understand that it will prove a colossal undertaking to discover some way by which the cancer cells may be penetrated and their cancer-producing molecules dehydrogenated; still, one can but try. In conclusion, I beg strongly to suggest that the various groups of

scientific men who are now studying the cancer problem, and who have up to this been working largely in watertight compartments, be brought together into one coherent organized body under one head directing staff; that every class of scientific worker should be incorporated into this body, which should consist of cytologists, pathologists, biochemists, and geneticists, as well as a number of scientifically minded practical medical men.—I am, etc.,

Kirk Michael, Isle of Man,
June 29th.

E. G. FENTON.

The Ante-natal Use of Quinine

SIR,—In my original paper on "The Use of Quinine in Normal Labour" (*British Medical Journal*, 1930, i, 144) I made a special appeal to those who controlled large numbers of maternity cases to give the method a serious trial, and I was naturally pleased to see that such a trial had been made at Queen Charlotte's Hospital. On the whole, I am not displeased with the findings summarized by Dr. F. W. Buddee in his paper in the *Journal* of June 30th (p. 1159) upon this subject. It is possible, however, that the findings might have been even more satisfactory and more in accordance with those described in my own paper if the method followed by Dr. Buddee had not been "modified" from the original one. It was stipulated in my paper: (1) that there must be an optimum dose (probably $4\frac{1}{2}$ to 5 grains daily); and (2) that this amount should be given in divided doses ($1\frac{1}{2}$ grains three times daily before meals was suggested).

Such a dose as 5 grains of an absorbable salt like the acid hydrochloride can even bring on a "storm of contractions," as shown by Conitzer in 1907, and may be even responsible for some of the premature labours which occurred in Dr. Buddee's series. With regard to the duration of labour, no comparison between his series and mine can be made because he refuses to draw any distinction—even arbitrary—between "true" and "niggling" (or "false") pains, and it seems to me that we can never make any progress in the comparison of labour cases until some such distinction is generally accepted. Further, the Queen Charlotte's series was vitiated by the inclusion of seven cases of occipito-posterior positions requiring manual rotation, and although it would be interesting to test a large series of such cases both with and without ante-natal quinine, their inclusion in this series only confuses the real point at issue. It would be interesting to know whether any of the "several bad cases of inertia" quoted by Dr. Buddee were associated with these occipito-posterior positions, or with other complications, such as "large child," hydramnios (even relative), or other primary causes of inertia.

In spite of these few points of criticism I welcome Dr. Buddee's paper as a genuine attempt to get at the real scientific truth.—I am, etc.

Bath, July 4th.

DOUGLAS A. MITCHELL.

Psychological Effect of Hysterectomy

SIR,—Dr. Winifred Coppard, whose letter appeared on June 9th (p. 1048) may be interested in the following case.

Three years ago I saw a patient (aged 30) whose main symptom was bleeding during coitus. Examination revealed a severe type of cervical erosion. A piece was removed and submitted to a competent pathologist, who reported the condition as malignant. I performed a pan-hysterectomy, and recently the patient presented herself for her six-monthly examination. In view of Dr. Coppard's letter I questioned the patient concerning her

sexual habits and found that both she and her husband experienced pleasure during coitus.

One would probably misapply Terence's meaning in writing "Quot homines, tot sententiae," but the case of the impotent husband, mentioned by Dr. Coppard, carries one's mind towards the writings of Krafft-Ebing and the necessity, under certain circumstances, of wearing high-heeled buttoned boots.—I am, etc.,

NOEL BRAHAM.

Gosport, July 7th.

Occupational Dermatitis

SIR,—A few days ago I had referred to me a case of alleged "dermatitis produced by dust or liquids," and that reminded me of the article by Dr. P. B. Mumford in the *Journal* of May 12th, and of the letter from Dr. MacKenna in the issue of May 26th. My perspective in viewing the subject is probably different from theirs, and what I write now is not a matter of criticism, but simply musings on some facts from my own experience as medical referee and assessor for a number of years.

The subject of skin diseases is difficult, and perhaps not least so in regard to aetiology: nomenclature, too, is fluid. I have always thought that, as Dr. Mumford says, "the exact interpretation of the word 'dermatitis' is not clear even to dermatologists," and also "that 'dermatitis' is an extremely loose word, of no watertight definition."

Looking up my records since the beginning of 1932 I find I have thirteen cases of "dermatitis produced by dust or liquids" referred to me. One may be disposed of in a class by itself, my decision being that the workman had the scheduled disease when examined by the factory surgeon but not when examined by me, and that the disability had ceased on a certain date. Of the remaining twelve cases six were decided in favour of the workman and six against. It may well be that, as no professed dermatologist, I made decisions which were equally wrong in both series of cases. In the series decided in favour of the workmen no medical evidence was submitted in one case, in three cases evidence tending against was submitted, and in two cases evidence both for and against. In the other series there was no evidence in three cases, in two cases evidence nominally against, but really of no value, and in one case evidence for and against.

I do not think it is quite recognized by all readers, nor by some writers, what, as Dr. MacKenna says, is "the power which is at present given under the Workmen's Compensation Act to the medical referee." It may be news to them to be told that he has not to decide whether the disease was acquired in, or is due to, his occupation; he has not even to decide whether it is an occupational disease; all he has to do is to give his opinion as to whether the workman is suffering from "dermatitis produced by dust or liquids," and "whether he is thereby disabled from earning full wages at the work at which he was employed." If he decides affirmatively the onus is put upon the workman of proving that the disease arose from his occupation. Thus Dr. MacKenna is wrong when he says "the ultimate responsibility for adjudication devolves upon a referee." He is right technically when he says that "a referee without reference to other medical men can [my italics] adjudicate in cases of occupational dermatitis"—right technically, but wrong in essence, because the medical referee is required to notify both workman and employer of time and place of the examination, and the notification in each case bears these words: "Any statement made or submitted by you shall be considered." Thus, from the very beginning, the medical referee has to place himself in the position "to hear medical evidence in support of their case."

Dr. Mumford's "Interpretation in Certain Cases" has paragraphs of the greatest interest scientifically, but he reduces the problem of the medical referee to almost nothing when he follows up with "the law reads that acceleration or aggravation by work of a disease entitles the workman to compensation." Dr. Mumford concludes that he "has yet to be concerned in a case where there was real divergence of dermatological opinion, however wide the breach may appear to become after skilled examination and cross-examination by experienced barristers." Over many years as medical assessor (and not in skin cases only) I have been interested, amused, and sometimes pained to see how barristers will lead a medical witness up the path, and how often he has simply to leave a gate ajar for the witness to make a path for himself. During the same years as referee, where the "big bad wolf" of a barrister has not yet intruded, it is wonderful to find how one medical report cancels another, and, indeed, sometimes how one part cancels another of the same report.—I am, etc.,

Hull, July 2nd.

JOHN DIVINE.

Hereditary Scoliosis

SIR,—The possibility of the hereditary nature of scoliosis, as suggested by Dr. Hugh Garland in the *Journal* of February 24th (p. 328), was discounted in subsequent correspondence. It is, no doubt, wise to receive fresh suggestions with a degree of judicious scepticism, but the appended pedigree, from a collection of unpublished materials that has been accumulating for over twenty-eight years, may help to confirm Dr. Garland's conclusion and to dispel scepticism.

This chart shows three cases of scoliosis in direct descent in three generations—mother, daughter, and

granddaughter. The person affected in the first generation died at an advanced age (84 years) from tabes dorsalis and blind from double optic atrophy. She had three children: the eldest died in infancy; the third died when six months old; the survivor is still alive and is deformed with a very definite degree of scoliosis. The patient affected in the second generation had six children. The first was premature and died when 9 months old. The second died at the age of 14 years. The third was killed in the European War, and would probably have been rejected for military service and stayed safely at home if he had been deformed. The fourth is in Australia, and is said to be normal, but this cannot be verified. The fifth is normal. The sixth (a woman aged 28 in 1934) has scoliosis, as have her mother and her grandmother.

A surgeon to whom I have shown this pedigree asserts that he sees in it no heredity but only rickets, going on to comment on the influence of three generations of city life and a slum environment. The first two generations in this family were country born and bred; the third generation was city born, but has not lived in the slums. None of the surviving members of this stock who reside in England show obvious stigmata of rickets, which would be acting in a strange manner if it occurred selectively in the dorsal spine in three successive generations.—I am, etc.,

Manchester, July 2nd.

W. J. RUTHERFORD.

Advertisements of Sex Literature

SIR,—The present year has been marked by an inundation of advertisements of a peculiarly obscene type, directed, we presume, particularly towards the medical profession. We are glad to see that the law has recently marked its disapproval of such methods by the infliction of a penalty under the laws which control the dissemination of obscene literature through the post.

The need for this type of literature, which deals with sex and the *ars amoris*, does not at once seem apparent to those whose practice lies along different lines, among relatively normal people. What useful function it fulfils we are at a loss to understand; but we would be interested to know whether some of our colleagues who sponsor such work consider it to be a serious contribution to science. It seems to us that the reading of such erotic nonsense by many young people would be more likely to lead to the creation than to the correction of those sexual neuroses which form the main excuse for offering it to the public.—We are, etc.,

HECTOR M. WALKER.

A. MORRIS JOHNS.

London, W.1, July 9th.

Rasputin's Death

SIR,—I have been interested for a considerable time, in common, I imagine, with many other medical men, in the incidents described relating to the death of the celebrated figure Rasputin.

It is recorded that on December 29th, 1916, an attempt was made to poison him, and after this had proved unsuccessful he was shot with a revolver, his body later being thrown into the River Neva. We are given to understand that the poison used was cyanide of potassium, and the problem of particular medical interest arises when we consider how it can have happened in this case that the attempt was ineffective, as it is a well-known fact that potassium cyanide is one of the deadliest of poisons, and is stated to have been administered to Rasputin in doses many times exceeding the fatal dose, both through the medium of chocolate cakes and in wine. In Prince Youssoupoff's book it is described how

"Dr. Lazovert put on rubber gloves and took out the crystals of cyanide of potassium. He crushed them, and, having removed the upper layers from the chocolate cakes, sprinkled each of them with a strong dose of poison, afterwards replacing the tops."

Three of these cakes were consumed by Rasputin and three glasses of poisoned wine.

Cases are recorded in books on toxicology of recovery from cyanide poisoning after amounts have been taken considerably greater than the fatal dose, but this, I believe, has occurred only after vomiting has ensued, or when prompt treatment has been administered. Rasputin apparently showed no sign of sickness after partaking of the cakes and wine, seemed, in fact, to suffer little or no ill effects of any kind, and although the usual fatal period for this poison is under five minutes, he was alive and in vigorous health over two hours later. Even allowing generously for individual variation, this is an astonishing fact, which obviously demands further elucidation. Leaving speculations of a supernatural character aside, it is interesting to consider whether, as has been suggested, Rasputin may have had an immunity to the cyanides similar, we may suppose, to the immunity of rabbits to belladonna. One cannot altogether dismiss the possibility, but it is extremely unlikely, although for obvious reasons difficult of proof.

It is known that fats may delay the action of drugs, but it is incredible that even if Rasputin had partaken of a fatty meal beforehand this would have proved suffi-

cient to counteract the effect of so powerful a poison. Probably, however, the real explanation is that Rasputin never received the poison at all. There seems to be no doubt that he swallowed some substance assumed to be cyanide of potassium, but by far the most likely solution of the mystery is that the powder, whatever its nature, was not what it purported to be. If this is established as the most credible view it will go far to dispel the atmosphere of awe and mystery with which, in the minds of the superstitious, this historical figure is surrounded, and also afford an explanation of an outstanding medical enigma. Perhaps a toxicologist may be able to shed further light on the problem.—I am, etc.,

London, N.4, June 28th.

FREDERICK DILLON.

* * The suggestion is made in a recent book, *Clinical Toxicology*, by Professor Erich Leschke of the University of Berlin, that the reason why Rasputin was immune from the effects of such a large dose of potassium cyanide was that he suffered from alcoholic gastritis. This, by absence of gastric hydrochloric acid, would inhibit the liberation of hydrocyanic acid, while absorption would be hindered by the thickening of the stomach mucous membrane.

British Health Resorts

SIR,—We have been much encouraged of late by the increasing interest shown in the work of the British Health Resorts Association by the medical profession. Our association is largely medical, not only in personnel but in its objects, which are to awaken and sustain interest in the health side of our British resorts. At our recent conferences at Harrogate and Cromer we were supported by leaders of the profession, and I venture to think that the quality of the discussions was something of which we may be proud.

Though we look in the main for financial support to the local authorities of the places we are trying to help, we are very anxious to secure more of it from the medical profession, particularly from those members practising in the health resorts or who take a special interest in climatology, balneology, and physical medicine. The recent action of the Harrogate Medical Society and the Torquay Division of the B.M.A. has therefore given our council great pleasure. These bodies have circularized their members with a view to enlisting their interest in our work, and by this means we have secured a considerable number of new members. Our Medical Advisory Committee would be glad to have an opportunity in your columns of bringing these examples to the notice of similar bodies, in the hope that they may do likewise.

Our subscription is £1 1s. a year, though we would welcome any donations, small or large. We cannot offer any direct material advantage to subscribers, but we believe there are many who would be willing to show a practical interest in a movement which has a distinctly medical as well as a patriotic aim. I shall be glad to answer any inquiries.—I am, etc.,

ALFRED COX,

General Secretary, British Health
Resorts Association.
199, Piccadilly, W.1, July 2nd.

The Medical Directory

SIR,—To maintain the accuracy of our annual volume we rely upon the return of our schedule, which has been posted to each member of the medical profession. Should the schedule have been lost or mislaid we will gladly forward a duplicate upon request. The full names of the doctor should be sent for identification.—We are, etc.,

J. AND A. CHURCHILL, LTD.

Publishers of *The Medical Directory*.

40, Gloucester Place, Portman
Square, W.1, July 2nd.

The Services

HONORARY PHYSICIAN AND SURGEON TO THE KING

Surgeon Vice-Admiral R. W. B. Hall, C.B., O.B.E., has been appointed Honorary Physician to the King.

Surgeon Rear-Admiral W. W. Keir, C.M.G., has been appointed Honorary Surgeon to the King.

CENTRAL COUNCIL OF SICK BERTH STAFF ASSOCIATIONS

Recently a meeting was held at the Medical Department, Admiralty, under the presidency of Surgeon Vice-Admiral Sir Reginald Bond, when a Central Council of the Royal Naval Sick Berth Staff Associations at Portsmouth, Plymouth, and Chatham was formed under the patronage of Admiral of the Fleet Sir Roger Keyes.

The main object of the Central Council is to assist the sick berth staff to find employment on retiring from the Service. This year there will be 110 of them, owing to the large number who were recruited in 1912. These associations have up to date managed their own affairs, mainly to provide death and invaliding benefits, as well as assisting in obtaining employment on discharge from the Service. Each will still manage its own financial affairs, but with the Central Council's assistance it is considered that the employment question will be more forcibly brought to the notice of the medical and general public.

The Royal Naval Sick Berth Staff are trained men who act as nurses in Royal Naval Hospitals and ships in the Navy. They have to pass examinations for promotion, and are discharged to pension after twenty-two years' service. They have considerable experience in responsible positions. Many have qualified as masseurs, radiographic, laboratory, electrotherapeutic, and operating theatre assistants. All have experience in dispensing and store-keeping, as well as surgical, medical, and mental nursing, and so are qualified to fill various situations in hospitals, clinics, institutions, etc., as surgical assistants, or as assistants to medical men.

Surgeon Vice-Admiral R. W. B. Hall, Medical Director-General, is a vice-patron, while Sir Reginald Bond is the president, and Surgeon Captain Montague Knapp, C.O. Medical Department, Admiralty, London, S.W.1, is the representative president, who will be glad to furnish any further information.

MENTIONED IN DISPATCHES

The names of the following have been brought to notice by His Excellency Field-Marshal Sir Philip W. Chetwode, Commander-in-Chief in India, for distinguished services rendered in connexion with military operations against the Upper Mohmands, period July 25th to October 3rd, 1933: Colonel E. W. C. Bradfield, C.I.E., O.B.E., I.M.S., Assistant Director of Medical Services, Peshawar District; Majors F. R. H. Mollan and A. E. Richmond, O.B.E., R.A.M.C.; Major D. V. O'Malley, O.B.E., I.M.S.; Captain S. D. Dahl, I.M.S.; Lieutenant J. O'Neill, I.M.S.

DEATHS IN THE SERVICES

Colonel Ernest William Bliss, C.M.G., D.S.O., late R.A.M.C. (ret.), died at Portsmouth on May 14th, aged 64. He was born at Leamington on September 19th, 1869, the son of the late Rev. William Bernard Bliss, was educated at Dudley Grammar School and at Mason and Queen's Colleges, Birmingham, took the M.R.C.S., L.R.C.P. Lond. in 1892 and entered the R.A.M.C. as lieutenant on January 28th, 1897. He was specially promoted to captain for services at the Battle of Khartum, from November 16th, 1898, for a brief lieutenant-colonelcy on February 18th, 1915, and became substantive lieutenant-colonel eleven days later, in the long war promotion list of March 1st, 1915. He became colonel on December 26th, 1917, and retired on December 26th, 1923. He served in the Nile campaigns of 1897-8, was present at the battles of the Atbara River and Khartum, was mentioned in dispatches in the *London Gazette* of May 24th and September 30th, 1898, specially promoted to captain, and received the medal, with two clasps, and the Egyptian medal. In the war of 1914-18 he served in France and

Flanders, as A.D.M.S., and later as D.D.M.S., of the Second Army Corps, was five times mentioned in dispatches, in the *London Gazette* of February 17th, 1915, January 4th, 1917, May 29th, 1917, December 24th, 1917, and December 30th, 1918, and received the D.S.O. in 1917 and the C.M.G. in 1918, also the Legion of Honour and the Croix de Guerre. After the armistice he served as D.D.M.S. of the British Army on the Rhine. He married Florence Ruth, daughter of the late Thomas Graves, solicitor.

Major George Raymond, R.A.M.C. (ret.), died at Devonport on May 12th, aged 75. He was born at Tralee on April 8th, 1859, was educated at Trinity College, Dublin, where he graduated B.A. in 1884, M.B., Ch.B. in 1885, and took the D.P.H. in 1903, and entered the R.A.M.C. as surgeon on February 5th, 1887. He became major after twelve years' service, and retired on June 27th, 1908. He served in the Sierra Leone campaign of 1898-9, in the Mendiland expedition, receiving the medal with clasp; and in the South African War in 1899-1901, when he took part in operations in the Orange River Colony and in the Transvaal, and received the Queen's medal with three clasps.

Universities and Colleges

UNIVERSITY OF OXFORD

The Theodore Williams Scholarship in Pathology, 1934, has been awarded to D. F. G. Moir (Magdalen).

UNIVERSITY OF LONDON

A meeting of the Court was held on July 4th, with the chairman (Lord Macmillan) presiding. The Court considered the tenders from seven selected firms for the superstructure of the first of the buildings to be erected on the University's site in Bloomsbury. The lowest tender received—namely, that of £362,579, from Messrs. Holland and Hannen and Cubitts—was accepted. A condition of the contract will be the use throughout of materials obtained from sources within the British Empire. The contract now to be entered into will provide for the building of the Senate House and administrative offices, a portion of the University Library, and certain works connected with the University Hall; but the University will have the option to extend the contract to cover additional works. The date for completion is March 25th, 1936.

The Senate has nominated Lieut.-Colonel J. R. Forrest, R.A.M.C. (ret.), for appointment as governor of the Purley County Secondary School for Boys.

The following have been recognized as teachers of the subjects indicated in parentheses, and have been assigned to the Faculty of Medicine: Dr. W. M. Goldblatt (Physiology), St. Thomas's Hospital Medical School; Mr. W. D. Doherty, Mr. N. L. Eckhoff, and Mr. G. Massie (Surgery), Dr. L. Forman (Dermatology), Mr. G. F. Gibbard (Obstetrics and Gynaecology), Dr. A. C. Hampson (Medicine), Mr. V. E. Lloyd (Venereal Diseases), Guy's Hospital Medical School; Mr. M. F. Nicholls (Surgery), St. George's Hospital Medical School; Dr. A. Burnas (Dermatology), Mr. A. M. A. Moore (Surgery), London Hospital Medical College; Dr. Alan Moncrieff (Diseases of Children), Middlesex Hospital Medical School; Mr. C. W. Flemming and Mr. A. J. Gardham (Surgery), Mr. M. L. Forbny, Mr. H. A. Kisch, and Mr. F. W. Wathyn-Thomas (Oto-rhino-laryngology), Dr. W. N. Goldsmith (Dermatology), Dr. M. Mairéls (Pathology), Mr. C. D. Shapland (Ophthalmology), Mr. N. L. White (Obstetrics and Gynaecology), University College Hospital Medical School; Sir Norman G. Bennett, M.B., B.Ch. (Dental Surgery), London School of Dental Surgery.

The Senate on June 20th resolved to institute a University Chair of Chemical Pathology, tenable at London Hospital Medical College.

A resolution was passed by the Senate conveying to Professor Karl Pearson its cordial thanks for his gift of £440 to establish a fund for statistical and allied topics.

Professor C. Lewitt Evans, F.R.S., was appointed a member of the University College Committee, as from October 1st, for the remainder of the year ending February 28th, 1935, vice Professor E. B. Vincent, who has resigned as from September 30th, the date of his appointment to the School of Botany in Pharmacology in the University of Cambridge.

Graham Legacy

The Senate received the annual report of the Graham Legacy Committee for the year ending August, 1934, from which the following are extracts:

1. The general purpose for which the Graham Fund was founded is to aid research in the school of advanced medical studies connected with University College Hospital, and the Fund has for its object the prevention, cure, and alleviation of human disease and suffering.

2. The Graham Scholarship has been held by Dr. C. L. Oakley, and, since April 1st, by Dr. E. S. Duthie.

3. The activities of the laboratories continue along the usual lines. Apart from the gentlemen who receive definite grants for the expense of their investigations, most of those engaged in research in University College Hospital Medical School are substantially assisted by the facilities and equipment provided by the Fund. Grants amounting to £90 were made by the committee to seven workers, who have been engaged in the following inquiries: C. Bolton, (a) absorption from the intestine, (b) acidity of the stomach; A. E. Boycott and C. L. Oakley, transfusion; G. R. Cameron, inflammation in lower animals; G. R. Cameron and C. L. Oakley, tissue reaction to grafts; E. S. Duthie, antimucic sera; J. W. McNee, the pathology of the spleen and liver; F. H. Teale, humoral and cellular immunity.

Professor A. E. Boycott, F.R.S., was reappointed director of research under the Charles Graham Medical Research Scheme for a period of one year from September 1st. Dr. A. M. H. Gray has been elected chairman of the Graham Legacy Committee for 1934-5.

LONDON HOSPITAL MEDICAL COLLEGE

The "Price" Entrance Scholarship in Anatomy and Physiology, value £100, open to students of the Universities of Oxford and Cambridge, has been awarded to C. B. Willey of Balliol College, Oxford.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—N. L. Corkill, V. C. Cornwall, J. M. Erskine-Young, L. Findlay, H. G. Hanley, E. Hughes, E. R. Jones, D. H. Mills, G. W. Phillips, E. R. Smith.

M.B., Ch.B.—¹ Margaret F. Procter, ² E. W. Jones. *Part B (1924 Regulations):* A. B. Concanon, T. H. Pierce. *Part III (1929 Regulations):* Bessie Dodd, Jannett C. Evans, Kathleen M. Kavanagh, J. L. Lancelley, Annie A. Merrick, W. J. D. Scott. *Part I:* L. V. Arundel, D. Barton, C. H. H. Bryson, P. S. Byrne, H. Cantor, Eunice M. Clapham, J. B. David, T. M. Doran, Mabel M. Drummond, Beryl Edgcombe, G. H. Elledge, A. Fairbairn, H. Gewater, ³ J. Gill, ⁴ F. Harwood, ⁵ L. Henry, G. E. Hesketh, A. B. Higginson, Clarice Hughes, Gwendolien M. Hughes, T. Laithwaite, J. Leiper, ⁶ H. R. W. Lunt, K. S. E. MacRae, J. V. Manning, N. E. Mawby, G. D. Owen, Kathleen M. Pearson, M. N. Phillips, G. Platt, B. Polonsky, D. M. Rosenfeld, A. Simpkin, ⁷ A. Singer, W. S. Sutton, A. C. T. Vaughan, Joan Watts, R. E. D. Wheeler. *Passed in Individual Subject:* R. P. Harbord, F. Lancelley, T. E. Whitby (Pharmacology and General Therapeutics). *Part II:* Agnes Y. Bowie, ⁸ A. C. Brewer, J. L. Brown, ⁹ A. Cohen, G. V. Craine, C. F. Crampton, H. W. F. Croft, H. R. G. Davies, Phillis Dingle, ¹⁰ V. K. Drennan, B. J. Green, S. G. Griffin, R. L. Hartley, Clarice Hughes, ¹¹ J. E. E. Hughes, Mary M. Hurst, G. E. Jones, Joan G. Jones, E. W. Knowles, H. S. Lancelley, Ethna W. Little, Sheelah Little, G. B. Marsden, A. G. H. Menzies, F. R. Neubert, ¹² W. Parke, Margaret I. Roberts, ¹³ J. G. Rogers, A. R. Sibbald, Henrietta Sloan, E. G. Watson.

D.P.H.—Part I: G. McLoughlin. *Part II:* G. Clark, ¹⁴ T. L. Hughes, E. R. Jones, J. A. Jones, F. Langford, E. R. Smith, ¹⁵ V. J. Woodward.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—Part B: T. N. Fogarty, J. W. H. Foy, S. K. Sahay.

DIPLOMA IN TROPICAL HYGIENE.—A. R. Arulpragasam, I. H. B. Ghosh, C. C. Ling, J. S. McMillan, T. A. Malone.

¹ Second-class honours. ² Distinction in Surgery. ³ Distinction in Obstetrics and Gynaecology. ⁴ Distinction in Pathology. ⁵ Distinction in Pharmacology and General Therapeutics. ⁶ Distinction in Forensic Medicine and Toxicology. ⁷ Distinction in Public Health. ⁸ With distinction.

VICTORIA UNIVERSITY OF MANCHESTER

In the Faculty of Medicine the status of Dr. C. Paget Lapage, F.R.C.P., has been changed from Lecturer to Reader in Diseases of Children, dating from September, 1934.

Dr. J. F. Heslop and Dr. E. Vernon have been appointed Demonstrators in Anatomy and Mr. J. Devine Demonstrator in Physiological Chemistry.

The following candidates have been approved at the examinations indicated:

M.D.—*By Thesis:* C. N. Aldred, Marguerite E. Cliffe, ¹ E. A. Gerrard, E. R. W. Gilmore, J. M. Greenwood, E. F. Hill (gold medal), G. Lapage, ² W. H. Newton, G. Ramage, B. R. Sandford. *By Examination:* B. Dunkerley.

Ch.M.—Branch IV: W. B. McKelvie.

*FR.M.S., Ch.B.—*³ D. H. Mackay, ⁴ H. Baker, Monica D. Boyle, A. S. Bullough, W. P. Carrill, N. Copeland, J. D. H. Cran, D. D. Cranna, Annie M. Dawson, I. H. Flack, N. Goldstone, H. Harris, Eileen M. Hughes, F. Janus, N. F. Kirkman, Amy B. de V. Mather, G. H. Moore, ⁵ E. L. Patterson, R. Spencer,

⁶ J. A. A. L. Woodhead. *Part I (Forensic Medicine and Hygiene and Preventive Medicine):* Monica D. Boyle, J. Charnley, Eleanor B. Clarke, Mary A. C. Cowell, T. F. Davey, F. P. Ellis, W. Fielding, F. I. Firth, S. Franks, E. Greenhalgh, G. D. Harthan, E. H. Heilpern, H. K. Higson, A. D. Hoffmann, L. L. Hudson, J. I. A. Jamieson, W. E. Kershaw, A. F. Mackay, R. Mallinson, J. L. Morgan, Annie Nelstrop, R. L. Parish, C. S. Parker, J. N. Parker, G. R. Rhodes, L. Margaret Ross, C. Royle, H. L. Settle, J. N. Shepherd, D. Shute, R. Thornley, H. J. Wade, J. R. Wardley, Margaret I. Williams.

* With commendation.

† With second-class honours.

‡ Distinction in Medicine.

§ Distinction in Forensic Medicine.

UNIVERSITY OF LEEDS

At a congregation held on July 2nd the honorary degree of D.Sc. was conferred upon J. Shaw Bolton, M.D., F.R.C.P., medical director of the West Riding Mental Hospital, and until recently professor of mental diseases in the University of Leeds; and upon Sir Robert Muir, M.D., F.R.S., professor of pathology in the University of Glasgow.

NATIONAL UNIVERSITY OF IRELAND

UNIVERSITY COLLEGE, CORK

The following candidates have been approved at the examinations indicated:

M.B., B.Ch., B.A.O.—V. J. Dillon (second-class honours), R. T. Ahern, R. G. Cross, G. A. P. Hurley, B. Hutch, H. L. Lentin, M. J. McCarthy, C. P. O'Flynn, M. J. O'Sullivan. *Part I:* J. Cogan, J. J. Hurley, T. P. O'Brien, T. P. O'Connor, D. G. O'Driscoll, Catherine M. Sullivan, T. Sutton. *Part II:* B. Buckley, D. J. Burgess, M. D. Hegarty, J. F. McCarthy, T. J. Mullins. M.D.—J. Magner, J. H. Stritch. M.Ch.—M. McSwiney.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Election to the Council

On July 5th four Fellows were elected into the Council to fill the vacancies occasioned by the retirement in rotation of Mr. Ernest W. Hey Groves, Mr. G. Grey Turner, and Mr. Hugh Lett, and by the death of Mr. R. P. Rowlands. The result of the poll was as follows:

	Votes	Plumbers
GEORGE GREY TURNER (Newcastle-on-Tyne)	803	6
ERNEST WILLIAM HEY GROVES (Bristol)	841	3
HUGH LETT (London Hospital)	734	43
WILLIAM GIRLING BALL (St. Bartholomew's)	584	61
Ernest Cranmer Hughes	445	27
Alfred William Sheen	298	6
Duncan Campbell Lloyd Fitzwilliams	240	10
Gwynne Evan Owen Williams	210	13

In all 1,995 Fellows voted, including 210 resident out of Great Britain and Ireland; in addition nine votes were found to be invalid, and two were received too late.

Mr. Girling Ball becomes substitute member of Council for the late Mr. Rowlands until 1938.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Prophit Scholarship for Research in Tuberculosis

The Royal College of Physicians invites applications for the above scholarship, which will be appointed as from October next. The scholar will be responsible for the conduct of a survey into the incidence and progress of tuberculosis in selected sections of the community, by clinical examination and tuberculin testing, over a period of years. Radiological examinations will also be carried out, but not necessarily by the scholar. A medical qualification and some experience of tuberculosis are required. The scholarship will be renewable from year to year, and is worth £500 per annum, with an allowance for expenses. Applications, which must be received before September 1st, should be addressed to the Assistant Registrar, Royal College of Physicians, Pall Mall East, S.W., from whom further particulars may be obtained.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly business meeting of the College, held on July 6th, the following candidates, who had passed the Final Professional Examination under the conjoint scheme with the Royal College of Surgeons in Ireland, were duly admitted licentiates in medicine and midwifery of the College:

C. K. Byrnes, J. F. Cotter, G. J. Kelly, Phyllis I. Kelly, Margaret McCarthy, D. D. O'Brien, R. V. Phillipson, Muriel M. Smiddy, M. L. Zlotover

Obituary

SIR JAMES K. FOWLER, K.C.V.O., C.M.G.,

M.D., D.Sc., F.R.C.P.

Consulting Physician to the Middlesex Hospital, King Edward VII Sanatorium, and the Brompton Hospital

James Kingston Fowler, who died on July 3rd, was born at Woburn, Bedfordshire, on March 11th, 1852. He was educated at King's College, London, where he held the Warneford Scholarship and Fellowship, and later became a member of Gonville and Caius College, Cambridge. His first qualification was the M.R.C.S. in 1874, the L.R.C.P. following in 1876. His university degree came in 1879. He was house-surgeon and house-physician at King's College Hospital in 1874-6, and house-physician at Addenbrooke's Hospital, Cambridge, 1877-9. After a brief period on the staff of the Westminster Hospital he was appointed pathologist and curator of the museum at the Middlesex Hospital, and in 1885 lecturer on pathological anatomy. In 1880 he was appointed assistant physician to the Middlesex Hospital, and physician in 1891, and he held the post of joint lecturer in the practice of medicine from 1899 until his election as consulting physician and emeritus lecturer in 1913. His connexion with Brompton Hospital for Diseases of the Chest began in 1880, and after some years as assistant physician he was promoted full physician.

In 1898 appeared his work on *Diseases of the Lungs*, written in conjunction with Sir Rickman Godlee. The idea of such a conjunction of physician and surgeon in writing a book on diseases of the lungs was to endeavour to present a continuous picture of medical and surgical aspects of pulmonary disease. In order to obviate any doubt that might arise as to which of the two was expressing an opinion or recommending a particular method of treatment, each chapter bore the initials of the author responsible for it. No subsequent edition of this jointly written book appeared. In 1921 Fowler published his monograph on *Pulmonary Tuberculosis*. This contained some matter already published by him, but much of it was new, and was presented in a novel and attractive way for students and young practitioners. It did not pretend to be an exhaustive treatise—more a guide to safe diagnosis and treatment. He used the title of the book with satisfaction because he had warred, he said, at first alone, for thirty years against the use of the terms "phthisis" and "consumption." He wanted to systematize the use of the term "tuberculosis," applying it to this disease with various locating adjectives—laryngeal, meningeal—to describe the exact nature of the lesion. The style of the book was based on Sir Thomas Watson's classical work, *The Practice of Physic*, on which Fowler was brought up. The book certainly gives a most readable and useful account of pulmonary tuberculosis. It is all the more attractive to

those for whom it was written because the reader is not bothered with a wealth of authorities—mostly at that date German. He wrote the articles on emphysema and syphilis of the lungs in Allbutt's *System of Medicine* in 1898 and 1909.

At the Annual Meeting of the British Medical Association in 1891 Fowler was vice-president of the Section of Pathology, and in 1903 vice-president of the Section of Medicine. In 1908 he delivered the Address in Medicine at the Sheffield meeting of the Association. This was the period when so much was being done with the opsonic index by Sir Almroth Wright and his followers, and, not unnaturally, the address, which was on vaccine therapy, dealt exhaustively with the subject. In that year he held office as president of the Medical Society of London, and he had been elected honorary physician to the King Edward VII Sanatorium. For some time he served on the Colonial Advisory Medical and Sanitary Committee and on the Committee on Colonial Medical Appointments. In 1913 he was appointed a member of the West African Yellow Fever Commission, having as colleagues Sir William Leishman, Sir Ronald Ross, and Sir William Simpson. The Commission was not to proceed to Africa, but to study and report on evidence collected by the various men working there. The reports were published in the following year.

Fowler was one of the senior members of the Senate of the University of London, and had served for a period as dean of the Faculty of Medicine. He was also a member of the Governing Body of the Lister Institute, and had been examiner in medicine for the English Conjoint Board and for the University of Cambridge.

He was created K.C.V.O. in 1910, after having been in attendance on the late Prince Francis of Teck, who had done very fine work for the Middlesex Hospital. There

had been some misconception about the illness of the Prince, in the treatment of which Sir Alfred Pearce Gould had been associated with Fowler, so the facts were published in the medical journals. Fowler was one of those who gave strong support to Marcus Paterson in starting graduated work in the routine treatment of pulmonary tuberculosis at Frimley Sanatorium, and he was much interested in the work of King Edward VII Sanatorium at Midhurst and the Papworth Tuberculosis Colony. In his earlier days he was consulted by Cecil Rhodes, who originally went to South Africa because he was thought to be threatened with tuberculosis.

On the outbreak of war in 1914 Sir James Fowler was on the *à la suite* staff of the 3rd London Territorial General Hospital, and he served for a time in France as consulting physician for the Rouen base with the rank of Colonel A.M.S. On returning to London he was attached to the Queen Alexandra Military Hospital, Millbank. He was awarded the C.M.G. for his services during the war.

Sir James Fowler was unmarried. At the Beefsteak Club, where he often dined in former years, he met

many prominent men. Before he was knighted he always insisted on being called "Mr.," his idea being that he might thus discourage conversation from drifting to medical subjects. One of his close friends was the late Sir Otto Beit, in whose benefactions for medical research he took a deep interest, and he was for many years one of the Beit Memorial Trustees and honorary secretary of that body. An intimate friendship with the second Lord Montagu of Beaulieu led Fowler to promise in an "incautious moment" to write a short guide to Beaulieu Abbey in the New Forest. He had had placed at his disposal unpublished manuscripts bearing on the history of the Abbey, and this led to a short guide becoming a monograph of 226 pages. *A History of Beaulieu Abbey, A.D. 1204-1539* (published in 1911) is a very fine and handsomely illustrated account of the Abbey of Bellus Locus Regis, as it was called in the original charter. Besides telling the story of the Abbey through the centuries, with pictures of what remains of it now and restorations of what it was in all its glory, the book gives an account of the Cistercian monks, who had founded this and seventy-four other abbeys and twenty-six nunneries in Great Britain by the time Wolsey and Henry VIII laid their heavy hands on the monasteries. The proceeds of the sale of the book were devoted to the care and maintenance of the building of the Abbey. Fowler lived in his later years of life when out of town at the Warden's Lodge, Beaulieu, and published in 1923 a much smaller work—*Hayles and Beaulieu: A Brief History and Guide to Hayles Abbey, a Daughter House of Beaulieu*. In his youth he was much interested in falconry, and used to go down to hawking meetings on Salisbury Plain.

[The photograph reproduced is by Elliott and Fry Ltd.]

ARTHUR BERNARD CRIDLAND, F.R.C.S.Ed.

Vice-President, Ophthalmological Society of the United Kingdom

The death of Mr. A. B. Cridland of Wolverhampton at the age of 61 years, on June 29th, came as a shock to a wide circle of friends and colleagues. The son of Mr. Arthur Cridland of Clifton, Bristol, he was educated at Clifton College, Bristol Medical School, and St. Mary's Hospital, London. He qualified M.R.C.S.Eng., L.R.C.P. Lond. in 1898, and later took the F.R.C.S.Ed. and the D.O.Oxon.

Cridland's appointment to the Bristol Eye Hospital as house-surgeon in the early 'nineties, when he came under the influence of Mr. Richardson Cross, determined his future career. In 1903 he was appointed house-surgeon at the Wolverhampton and Midland Counties Eye Infirmary, and shortly afterwards began to practise in Wolverhampton and Stafford. In 1904 he became honorary assistant surgeon to the Wolverhampton Eye Infirmary, and seven years later honorary surgeon, a post he held at the time of his death. A presentation of silver from the Managing Committee and Ladies' Committee was made to him and his wife in March, 1933, on the occasion of their silver wedding. In 1921 he was made consulting ophthalmic surgeon to the Royal Hospital, Wolverhampton, and when the ophthalmic department of the Staffordshire General Infirmary was inaugurated in 1905 he became its first honorary ophthalmic surgeon. During the past year he accepted a similar appointment to the Bridgnorth and South Shropshire Infirmary.

Mr. Cridland joined the British Medical Association in 1900, and was chairman of the South Staffordshire Division in 1927-8. He was vice-president of the Ophthalmological Society of the United Kingdom, and owing to the illness of the president presided at its last session in April of this year. He was also a vice-president of the Ophthalmic Section of the Royal Society of Medicine, and

a member of the French Ophthalmological Society. His past offices were numerous, notably Master of the Oxford Ophthalmological Congress for three years, president of the Midland Ophthalmological Society, and vice-chairman of the Council of British Ophthalmologists. He delivered the Middlemore Lecture at Birmingham in 1917, and the Doyné Memorial Lecture at Oxford in 1933. Special mention must be made of his most valuable services for fifteen years as honorary secretary of the Oxford Ophthalmological Congress. In this he was seen at his best, and was universally popular. When he retired the members, in an enthusiastic gathering, presented him with a gold watch and a canteen of silver. This well-deserved mark of appreciation of his work gave him the keenest pleasure, but it was characteristic of his modesty that he remarked to the writer that he did not think he deserved such a valuable present, as he had always enjoyed the work. When the International Association for the Prevention of Blindness was founded at The Hague in 1929, Cridland was appointed to represent Great Britain on the Executive Committee. He was also a member of the Union of Counties Association for the Blind and a medical referee on the Midland Circuit. During the South African War he was a civil surgeon to the Princess Christian Hospital of the Natal Field Force.

Truly this list of public activities is one of which any man might well be proud, and there is little doubt that the unsparring devotion he gave to them and to a large and successful private practice taxed his strength, and was a factor in bringing to an untimely end a most useful life and a very successful career. Practising as he did in a large industrial area, it was natural that he should be especially interested in injuries of the eye, and his Doyné Memorial Lecture dealt with "The Aftermath of Cases of Intra-ocular Foreign Body." Based on his own experience, it is the type of paper which is of lasting value. Cridland made other contributions to ophthalmic literature, a detailed mention of which space forbids, but one may just mention his interest in the use of the tonometer in its early days, and his advocacy of Lagrange's sclerectomy operation for glaucoma.

Bernard Cridland leaves a widow, two sons, and two daughters. It is pleasing to recall that he was very happy in his married life and devoted to his children. His wife usually accompanied him, when possible, to Oxford, where she was extremely popular with the members of the congress and their wives, and much sympathy will be felt for her in her sad loss by a wide circle of friends.

Lieut.-Colonel A. E. J. LISTER, F.R.C.S., I.M.S. (ret.), late professor of ophthalmology, King George's Medical College, Lucknow, writes:

On behalf of myself and many ophthalmologists practising or who have practised over-seas, may I be allowed to pay a brief tribute to the memory of my friend Bernard Cridland. Many of us looked forward to the Oxford Ophthalmological Congress on our next leave home, and not the least pleasant part of it was the genial welcome we always received from Cridland. He seemed to delight in making everyone happy. Nothing was too much trouble for him, yet he was never in the least fussy or obtrusive. What his work for so many years, as honorary secretary, meant to the Oxford Congress is now a matter of history, and was fittingly crowned by his being made Master of it in due course. We overseas members, after a first visit, all looked upon him as a friend, and if we wrote to him, as many did, we were sure of a prompt and helpful reply. Others will deal with other aspects of Cridland's career, but I am sure that these few words, however inadequate, will be endorsed by many ophthalmologists.

logists throughout the world. His wife was always his equal in friendliness and geniality, and it may be some slight consolation to her to know that many others will mourn with her when the news reaches them over-seas, and that their sympathy, though in many cases perhaps unexpressed, will be none the less real.

NEWMAN NEILD, M.B., F.R.C.P.

Physician, Bristol General Hospital

Dr. Newman Neild, senior physician to the Bristol General Hospital, died suddenly on July 4th, at the age of 62 years, deeply regretted in Bristol and the neighbourhood, where he was widely known.

Newman Neild was born in Manchester in 1872, where his father was principal of Dalton Hall. He was educated at Bootham School, York, and later entered, as a medical student, Owens College, Manchester, taking the degrees of M.B., Ch.B.Vict., with honours, in 1896. He held resident appointments at the Manchester Royal Infirmary, the Brompton Hospital for Consumption, and the Great Ormond Street Hospital for Sick Children. He settled to practise in Bristol, and in 1901 was appointed assistant physician at the General Hospital, where he laboured for nearly eighteen years as an out-patient physician without beds. In October, 1918, he was promoted to be full physician. He was for many years lecturer in charge of the department of pharmacology and therapeutics. In 1907 he became M.R.C.P.Lond., and in 1928 was elected a Fellow. He was an examiner for the Conjoint Board in materia medica and pharmacology from 1928 to 1932, and also in the University of Birmingham and Bristol. For many years he was honorary physician to the Clergy Daughters' School, Bristol.

He had rendered long and magnificent service to the British Medical Association as honorary secretary of the Bath and Bristol Branch (junior, 1905-13; senior, 1914-23); secretary and treasurer, Bristol Division, 1905-14; secretary only, 1915-22; president, Bath and Bristol Branch, 1923-4; representative, 1916-18 (London). His consideration for, and devotion to, his hospital patients bore witness to an inspiring zeal, which remained undiminished in spite of impaired health and a period of sanatorium residence.

Although immensely interested both in the practice and in the teaching of medicine, Neild was a man of many-sided interests. He was a clever, accurate pencil draughtsman, a connoisseur of paintings and engravings, a knowledgeable collector of china, and the proud possessor of a rare collection of old herbals and botanical books. He was of a cheerful disposition, and dearly loved a good story, whilst a satirical vein sometimes made his wit cut more deeply than he intended. Yet he always had a kindness of heart that showed in many ready acts of generosity and sympathy. Newman Neild was a sturdy fighter with a streak of obstinacy, which was occasionally of the greatest value in fighting the battles of the British Medical Association. He leaves a widow and two daughters, with whom deep sympathy is felt.

DAVID ROSS, M.D.

Past-Chairman, City Division

We have to record with regret the death on July 4th, at his home in Kingsland Road, London, E., of Dr. David Ross, who was well known to many members as a strong supporter of the British Medical Association and an active worker in the City Division. David Ross was born in 1872, and studied medicine in Aberdeen and at St. Bartholomew's Hospital. He graduated M.B., C.M. (Aberd.) with honours in 1894, and proceeded M.D. in 1898 with the highest honours. In addition to carrying on a large practice in the Kingsland Road, he maintained his con-

nexion with his university, being an interim examiner in materia medica. His capacity for organization found an outlet in work for the Hackney School Treatment Centre, of which he was honorary secretary and treasurer, and also in the proceedings of medical societies. He was a vice-president of the Hunterian Society, and honorary secretary (late president) of the Aesculapian Society. During the war he held a temporary commission in the R.A.M.C., and was later vice-chairman of the National Service Medical Board for the City of London. He was also closely connected with the Metropolitan Hospital, of which he had been honorary medical officer. He had published various papers on clinical topics. Dr. Ross joined the British Medical Association in 1909, and was a member of the Representative Body at the Annual Meetings at Cambridge, Glasgow, Portsmouth, Bradford, Bath, and the two London meetings. He had been chairman of the City Division, and was a member of the Council of the Association in 1920-1.

Dr. ERNEST WORLEY writes: By the not unexpected death of Dr. David Ross the City Division has lost one of its oldest and certainly its most active and respected member. Ross held every official position at one time or another—chairman, secretary, representative—and each with the greatest possible success. Known by those of us who knew him intimately as a man of wide and deep learning, he had travelled extensively—an extremely able and interesting debater at all our meetings, and one whose views were always worth listening to. His advice and help has always been one of our greatest assets during the last twenty years—a most loyal supporter of the Association, even though he would never have anything to do with the panel service. He never missed an Annual Meeting to my knowledge except through ill-health. The loss to the Division is incalculable. Ross was my oldest and most esteemed friend.

ALEXANDER THEODORE BRAND, M.D.

Driffeld

We regret to record the death, on June 23rd, of Dr. A. T. Brand; his passing removes one of the outstanding personalities of East Yorkshire. Born in Chicago in 1852, of Scottish parentage, he graduated M.B., C.M. with honours at Aberdeen in 1881, and subsequently studied in Vienna and in London. He obtained the degree of M.D. (Aberd.) in 1884, after starting practice at Driffeld in 1882, where he succeeded the late Dr. Eames. He retired in 1927, after forty-five years of busy and successful life in general practice, during which time he won the love and esteem not only of his patients but of the whole district, in the affairs of which he played a prominent part. Among his public appointments he held the post of medical officer to the Driffeld and District Poor Law Infirmary for many years, and his devoted work there will long be remembered. In 1901 he was made a justice of the peace for the Bainton Beacon Division, and continued to sit on the Bench until a few weeks from his death, at which time he was the oldest magistrate, both in age and in years of service, and filled the office of vice-president.

Dr. Brand was a member of the British Medical Association for nearly fifty-two years, being president of the East Yorks and North Lincolnshire Branch in 1902-3. During the war he held the rank of major in the R.A.M.C., and commanded the No. 2 East Yorks Field Ambulance; he had previously been awarded the Volunteer Decoration. His chief medical interest concerned the origin of cancer, upon which subject he had both read and written widely. He held firmly to the opinion that malignant disease was due to a micro-organism, and was always eager, even to the time of his death, to discuss this subject with a

colleague, and to set forth sound arguments in favour of the theory. His book on *Cancer: Its Cause, Treatment, and Prevention*, published in 1922, gives a clear exposition of his views on this subject. He was also joint author with his partner, Dr. J. R. Keith, of a valuable book—*Clinical Memoranda*—which contains most useful and original information, culled from his vast clinical experience in general practice. Apart from his professional work he was an enthusiastic Freemason, and an authority on the subject. He had held every office open to him, and was three times Worshipful Master of the 'Sykes Lodge'. He is survived by his second wife, four daughters, and a son, who is also in the medical profession, as a major in the R.A.M.C.

On June 21st the death occurred, in St. Thomas's Hospital, London, whither he had gone for treatment several weeks before, of Dr. ALAN DEED BRUNWIN, a senior consultant tuberculosis officer of the Lancashire County Council. He was 55 years of age, and resided at Lancaster. Dr. Brunwin graduated at Cambridge as M.A. in 1903, B.Ch. in 1906, and M.D. in 1909. He received his medical and surgical training at St. Thomas's Hospital. In 1910 he took the D.P.H. at Aberdeen. His early appointments were resident medical officer of the Denbighshire Infirmary, and then Government medical officer in Fiji. From experience in this island he contributed two papers to the *Journal of Tropical Medicine*: "Observations on Santonin Treatment of Dysentery," and "Some Aspects of Filariasis in Fiji." After a period as assistant medical officer of the Westmorland Sanatorium at Meathop he joined, in 1913, the medical staff of the Lancashire County Council as consultant tuberculosis officer. His appointment for several years was joint with Blackpool Corporation. From November, 1914, until February, 1919, he held a temporary commission in the R.A.M.C., and was heart specialist on the staff of the hospital at Etaples in France, provided and organized by the Order of St. John of Jerusalem, and of which Colonel C. J. Trimble, the present chairman of the Lancashire County Tuberculosis Committee, was in command. Brunwin published in the *Practitioner* in 1921 an article on "Electrocardiography on Active Service." On his return from war service he took control of one of the five large dispensary areas in Lancashire, containing a population of 267,000, and an acreage of 303,000, with a pulmonary hospital at Lancaster and dispensaries at Lancaster, Preston, and Chorley. His relations with the medical practitioners, medical officers of health, and medical officers of institutions were ever of the most friendly nature; his clinical abilities ensured the complete confidence of all his medical colleagues. With the late Dr. Logan Stewart he did the pioneer work in regard to the treatment of tuberculosis by artificial light at centres established in tuberculosis dispensaries, and the results were published jointly in *Tubercle*, 1928, under the title "Artificial Light Treatment at Tuberculosis Dispensaries in Lancashire." Dr. G. Lissant Cox, the central tuberculosis officer, writes: Brunwin came of a family long connected with the county of Essex. Urbane and kind, possessed of attractive social qualities and a sure knowledge of all aspects of his chosen specialty, tuberculosis, he will be greatly missed by all his colleagues, his patients, and his many friends.

We regret to record the death on June 27th of Dr. HENRY DARVILLE BROOK of Fareham, Hampshire. Born in 1862, he received his medical education at St. Thomas's Hospital, obtaining the diplomas M.R.C.S., L.R.C.P. in 1887. Public health attracted him early in his career, and he became D.P.H. in 1890. He was a well-known and popular resident in Fareham, where he was medical officer of health and public vaccinator. As lecturer and examiner for the St. John Ambulance Association he rendered exceptional service, and was appointed an honorary associate of the Order of St. John of Jerusalem. During the war he held the commission of lieutenant-

colonel in the R.A.M.C. T.A., as officer in command of the 2nd/3rd Wessex Field Ambulance, and was later A.D.M.S., 55th Division, B.E.F., in France, with the temporary rank of colonel. He held the Volunteer Decoration, and was a deputy lieutenant for Hampshire. One of Dr. Brook's outstanding hobbies was marksmanship, and he was a member of the Hampshire Rifle Association and the Portsmouth and District Rifle Club. He was also medical officer to the fire brigade, the Post Office, and the local industrial home. He was a member of the British Medical Association. The remains were cremated, and the ashes were scattered on the Bisley ranges in accordance with his special desire.

Dr. OCTAVIUS AUGUSTUS GLASIER COLLINS, formerly acting medical officer of health for Bath, died recently in that city at an advanced age. He received his medical education at St. Bartholomew's Hospital, where he qualified M.R.C.S. Eng. in 1882. In the following year he obtained the diplomas L.R.C.P. Lond. and L.M. of the Rotunda Hospital, Dublin, graduating B.C. Cantab in 1887. For many years Dr. Collins had been connected with the Bath Isolation Hospital, and up to the time of his death was consulting medical officer to the Eastern Dispensary. He had on various occasions assisted Dr. W. H. Symons, medical officer of health for Bath, and from 1917 to 1919 was acting medical officer of health. He retired from general practice in the early 'twenties.

Medico-Legal

AN "ENCYCLOPAEDIA OF SEXUAL KNOWLEDGE"

Summons by Director of Public Prosecutions

At Bow Street police court on June 28th, before Mr. Dummeth, the Amalgamated Publicity Services, Ltd., of Bucknall Street, W.C., appeared to answer a summons taken out by the Director of Public Prosecutions, charging them with having sent a postal packet enclosing indecent prints, contrary to Section 63 of the Post Office Act, 1908.

Mr. C. R. V. Wallace, who appeared for the Director, stated that on May 23rd a Mr. Murray, a solicitor, received through the post a pamphlet advertising a publication called "Encyclopaedia of Sexual Knowledge," and it appeared that a very large number of these had been dispatched. The attention of the magistrate was drawn to certain passages, and counsel submitted that the whole pamphlet was indecent.

Mr. Malcolm Hilbery, K.C., for the defendants, said that the case was not as simple as it might appear. The Act laid it down that indecent or obscene matter must not be sent through the post. He submitted that it was not the subject-matter of a publication which would make it indecent, but the manner in which it was treated. What was intended to be a plain statement, giving information, was not capable of being held to be indecent or obscene, but it must be something intended to affect the mind salaciously. The present pamphlet was no more than an absolutely plain statement on sexual topics. There had always been great differences of opinion as to how far sexual subjects should be frankly discussed, but to-day a considerable body of public opinion was in favour of the plainest talk. The same plain statements as appeared in the pamphlet were to be found in standard dictionaries under words connected with sex subjects, but it would not be suggested that the publishers of such dictionaries were circulating indecent matter. The only test, he could suggest was as to what the man of ordinary intelligence expected on reading something of this sort. The book, a bulky volume of fairly high price, was not intended for the prurient, but simply for the reasonable information of the public on a subject of high concern. It was impossible, of course, to approach such a topic without plain speaking, but while such approach was distasteful it need not be indecent.

Mr. A. Chadwick, chairman and manager of the defendant company, which had been in the publishing business for twenty-two years, said that his firm made careful inquiries beforehand as to the contents of the encyclopaedia and those responsible for its publication. The pamphlet was sent to

various classes of official and professional persons whose names were selected from directories. It was revised and extensively altered by the editor, Dr. Haire, before being sent out. The witness said he was chairman of the Public Library Committee of the Bromley Borough Council, and he produced a list of books available for borrowers in that library which dealt with sex education. The Library Committee took account of suggestions from readers, if satisfied that the desired books were proper ones. There was nothing in the encyclopaedia different from books in this public library. He added that rather more than a quarter of a million copies of the pamphlet had been circulated, but distribution ceased immediately the summons was received.

The magistrate said that he did not think this was a matter which should be decided hastily. He had not read the pamphlet, and he intended to keep a quite open mind until he had done so, and he would also try to get a little more light on the Section of the Post Office Act. He would give his decision in a week's time.

The magistrate gave his reserved decision on July 6th. He said that he had now had the opportunity of reading the pamphlet which advertised the "Encyclopaedia of Sexual Knowledge." So far as he knew, the book itself might be a scientific work, but the pamphlet stood on an altogether different footing. He was told that it had been circulated only to certain classes of people, educated people, who would not misunderstand what was intended to be conveyed. But the offence was that of sending indecent matter through the post, to whomsoever it was sent, and when it was put forward as a plea that it was only sent to certain classes of the community the implication was rather adverse to the defendants. The book might be a reputable work, but the pamphlet selected certain headings of chapters, and gave a preliminary account of certain subjects, emphasized by capital letters. The object of the pamphlet was evidently to increase the sale of the book by attracting the attention of members of the public whose interest in the subject was very far from being scientific. Accordingly he fined the defendants, the Amalgamated Publicity Services, Ltd., £10, and £3 3s. costs.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week debated agriculture, shipping, and colonial administration. The Shops Bill was down for report and third reading. A Standing Committee of the House began to examine the Betting and Lotteries Bill.

The South Middlesex and Richmond Joint Hospital District Bill, which has passed the House of Lords, was read a second time by the House of Commons on July 6th.

In the House of Lords, on July 10th, the Earl of Plymouth moved the second reading of the Road Traffic Bill. He said the Government had accepted an amendment in the House of Commons providing for the payment of fees to doctors in cases of emergency treatment. This was to be provided, irrespective of whether or not there was negligence on the part of the driver. It had been suggested that that was injustice, but, on the whole, the Government did not think it was comparable with the injustice which would be done to the medical profession if they were deprived of their fees in such cases. The Bill was read a second time.

General Medical Service

Mr. LEWELLYN-JONES, on July 5th, asked Sir Hilton Young if he was aware of a movement both in the medical profession and also among friendly societies and national health insurance organisations in support of the setting up of a complete medical service for the whole of the population of the country. Sir HURRY answered that proposals on this subject had been brought to his notice and were being examined. He could not indicate what action, if any, the Government might decide to take.

Expenditure on Medical Research

On July 9th Mr. DUFF COOPER, replying to Sir Robert Gower, said that the annual grant-in-aid of the Medical Research Council was £135,000 from 1925 to 1927 inclusive; £140,000 from 1928 to 1931 inclusive, and £139,000 in 1932 and 1933. Provision for a grant of £139,000 was included in the estimates for the current financial year. There were other contributions made by the State to medical research, but, apart from a grant of £100,000 in 1929 for the purchase of radium, it was not possible to give figures. Inclusive grants were paid to a number of universities, and considerable sums out of these grants were allocated by the university authorities to their medical schools, which included medical research among their activities. It was not possible to distinguish the amounts applied to this purpose. Medical researches were undertaken from time to time by the Ministry of Health and other Government Departments.

Research on Cattle Diseases

On July 9th, during the debate on the estimates for the Ministry of Agriculture, Dr. ELLIOT said that the estimates for the current financial year were for a net sum of £2,234,134. Of this £612,000 was for education and research and £180,000 for prevention of disease. The Department was expanding its staff to deal with what was recognized as an urgent necessity—namely, the saving of the great losses in the live-stock industry due to preventable disease. Mr. PERKINS asked the Minister what progress had been made in research into the cause and possible cure of foot-and-mouth disease. He suggested that instead of giving £16,500 every year to the various Government chemists and chemists in his Department, the Minister should offer a large bribe in the shape of a present of £250,000 or £500,000 to any individual chemist or biologist who could find out the cause of foot-and-mouth disease, and bring forward a definite cure. Sir W. WAYLAND asked if the Minister had any information to impart about John's disease, which was spreading through the country as it was throughout Europe. It meant the loss every year of an enormous number of cattle. There had been attempts at making various antitoxins, but they had not been successful. If more money were spent on research into the diseases of cattle and sheep we should not suffer the severe losses which we now did every year. Dr. Elliot said he could not give Mr. Perkins any definite information whether the Foot-and-Mouth Disease Committee had found out anything. It might be that the line which would give us a key to the problem was in some obscure research by a physicist who had no idea that he was working on anything that would be a key to a disease problem. He was a little dubious of the project of offering £250,000 or £500,000 as a gigantic prize. He had taken a note of what Sir W. Wayland had said about the necessity for continuing research, and particularly of the necessity for work about John's disease. Sir Merrik Burrell, who had given the Department a great deal of assistance, was working with his committee on all these questions of animal disease, and they had in him as capable an advocate of research as Sir W. Wayland would desire.

District Nursing Services

On July 10th Sir GERALD HURST obtained leave to introduce the Domiciliary Nursing Services Bill. He said that the Bill was intended to fill a gap in the existing laws which provided nursing facilities for the poor. Local authorities were not entitled at present to contribute to voluntary associations which provided district nurses for the care of the poor who could not pay for those services. In districts where there were no nursing associations the work of nursing unpaying patients went unfulfilled. Many cases of tuberculosis, cancer, and ulcer were, as a result, left without nursing. Owing to this disability imposed on the local authorities there was a shortage of district nurses. The Bill would enable local and county authorities to provide domiciliary nursing services for the inhabitants of their districts, to combine and pay nurses, to provide accommodation for them, and to make reasonable subscriptions and donations to voluntary associations.

Summoning a Doctor in Road Accidents

Mr. TEMPLE MORRIS, on July 9th, asked the Minister of Transport whether, in view of the proposed mulcting of a motorist of 12s. 6d. for the fee of a doctor when his car had been in collision with anyone, the doctor in each case would be summoned by the parties to the accident or by the police, and whether it was intended that any individual should have the right to communicate with a medical man. Captain AUSTEN HUDSON, who replied, said that the circumstances of accidents varied greatly, and a hard-and-fast rule on who had the right to summon medical assistance would involve dangerous delays.

Disease Carriers in Air Warfare

Mr. BALDWIN told Sir Nicholas Gratian-Doyle that the German Government had officially denied allegations that experiments were being made and plans perfected by the Luft-gas-angriff department for the destruction of human beings in war by aircraft carrying deadly disease germs, or that experiments had been made on the vulnerability of underground railways in London and Paris. The question of the vulnerability of underground railways in London was kept under constant observation as part of the general question of air raid precautions.

Safety Glass in Motor Vehicles.—Mr. HORE-BELISHA told Mr. Knight on July 4th that since January 1st, 1932, regulations had required, as regarded new vehicles, that all glass fitted to windcreens or windows facing to the front on the outside of any motor vehicle, except glass fitted to the upper deck of a double-decked vehicle, should be safety glass. He did not think it necessary to make use of such glass throughout public service vehicles compulsorily.

Pedal Cyclists in Road Accidents.—Replying to Viscountess Astor on July 4th, Mr. HORE-BELISHA said that the report on fatal accidents during the year 1933 showed that in that year 874 pedal cyclists were involved in fatal accidents which occurred in built-up areas. In 485 cases of fatal accidents in built-up areas the sole or main cause of the accident was the pedal cyclist.

Ambulance Services.—Sir HILTON YOUNG told Sir R. Gower, on July 5th, that a circular had been issued to local authorities last November on the general question of ambulance service. This was being followed by local investigations into the adequacy of the service in certain parts of the country. When he received the report on these investigations he would consider Sir Robert Gower's proposal to advise local authorities that applications from branches of the St. John Ambulance Brigade for the use of sites for casualty stations should receive favourable consideration from them.

Maternity Benefit and Poor Relief in Scotland.—On July 5th the House of Commons recommitted the Poor Law (Scotland) Bill. An amendment was moved to disregard maternity benefit in the assessment of Poor Law relief. Mr. SKELTON said he would accept the amendment, but its wording would have to be reconsidered in the House of Lords. The form of words as he suggested it at the moment ran:

"A local authority in affording outdoor relief to or in respect of any woman shall disregard the whole of any maternity benefit, exclusive of any increase of such benefit by way of additional benefit, or of any second maternity benefit to which she may be entitled under the last-mentioned Act, and the corresponding need shall also be so disregarded in the assessment of need."

The amendment thus worded was accepted, and the Bill passed through committee, report, and third reading.

Silicosis Disablement in South Wales.—Mr. ERNEST BROWN told Dr. John Williams on July 10th that between June 1st, 1931, when the Medical Board under the compensation scheme was appointed, and May 31st, 1934, 105 miners were certified by the Board as disabled from silicosis in the county of Carmarthen, and 279 in the remainder of the South Wales coalfield. The numbers of deaths certified by the Board were 26 and 37 respectively.

Medical News

The sixteenth annual meeting of the Mental Hospitals Association will be held in the Council Chamber of the Guildhall, London, on Wednesday, July 18th, at 11 a.m. A discussion on the working of the Mental Treatment Act, 1930, will be opened by Dr. J. Bain and Dr. F. J. Stuart; and a discussion on the Board of Control memorandum on occupation therapy for mental patients by Dr. R. Eager and Dr. J. I. Russell.

The annual meeting of the Society of Chemical Industry will be held in Cardiff from July 16th to 20th. The title of the presidential address of Dr. J. T. Dunn on the morning of Tuesday, July 17th, is "Science and Industry—the Fertility of Ideas," and that of Sir Harry McGowan's Messel Medal Lecture "The Uneven Front of Research."

The annual meeting of supporters of the Papworth Village Settlement, Cambridge, was held on Wednesday, July 11th, at 4 p.m., at the Park Lane Hotel, London, with the president, Sir Humphry Rolleston, in the chair. H.R.H. the Duke of Gloucester will visit the Settlement on Thursday, July 26th, at 12.15 p.m., to inaugurate the Bernhard Baron Memorial Hospital, afterwards laying the foundation stone of the surgical block.

The Fellowship of Medicine (1, Wimpole Street, W.) has arranged lecture-demonstrations at 11, Chandos Street, W., on July 17th and 24th, at 2.30 p.m.; and, with the exception of August 7th, they will be continued throughout August. Demonstrations for M.R.C.P. candidates, at 11, Chandos Street, on July 18th and 19th, at 4.30 p.m. and from August 13th to 17th, at 2.30 p.m. Particulars are given week by week in our *Supplement*, in the *Diary of Post-Graduate Courses*.

The Medical Society of Bad Nauheim will hold a post-graduate course from September 20th to 23rd on myocardial diseases. Further information can be obtained from the secretary of the society, Adolf Hitlerstrasse 16 Bad Nauheim.

The twenty-third Congress of Russian Surgery will be held at Leningrad from August 29th to September 6th when the following subjects, among others, will be discussed: shock; non-tuberculous affections of the lungs thrombosis and embolism; lesions of the hand and finger and their treatment; and extra-articular arthrodiesis. Further information can be obtained from the secretary of the congress, Bolchaia Pirogovskaia 6, Moscow.

The first International Congress of Electro-radio-biology will be held at the Ducal Palace at Venice from September 10th to 15th, under the presidency of Count Volpe de Misurata. Further information can be obtained from Dr. Giscondo Protti, Canal Grande S. Gregorio 173 Venice.

A meeting of the court of directors of the Society for Relief of Widows and Orphans of Medical Men was held at 11, Chandos Street, W., on July 4th, when Dr. W. Culver James, senior vice-president, was in the chair. The death of a member was reported, and two new members were elected. The sum of £2,285 13s. was voted for the payment of the half-yearly grants to the fifty-four widows and eight orphans in receipt of relief, including £105 13s. as special grants to assist orphans in their studies for professional or business careers. A letter from a widow was read expressing her great gratitude to the society for the help she had received to enable her son to qualify as a doctor. She had received twenty-five guineas a year for this purpose for the past five years. The directors again wished to bring the advantages of membership before the junior members of the profession. Relief is granted only to the widows or orphans of deceased members who are left in indigent circumstances. Membership is open to registered medical men who, at the time of their election, are residing within a twenty-mile radius of Charing Cross. Full particulars may be obtained from the secretary, 11, Chandos Street, W.1.

In our advertisement columns this week the Association of Surgeons of Great Britain and Ireland invites applications for a surgical scholarship of the value of £350 to be held for one year. The election will be made in November, and applications must reach the honorary secretary of the association, Mr. Julian Taylor, 65, Portland Place, W., by September 30th.

The seventh annual general meeting of the British Paediatric Association was held at Windermere on April 27th and 28th, under the presidency of Dr. Eric Pritchard, and a report of the proceedings appears in the current issue of the *Archives of Disease in Childhood*.

At a garden fête held at Morland Hall, Alton, on Saturday, July 7th, in aid of the Morland Hall Cot Fund at the Treloar Cripples' Hospital, the Countess of Radnor opened the new west wing of the clinics, which embodies several novel features in hospital construction. Among these is a method of giving natural sun treatment in the seclusion of the patient's own room, and without the necessity of wheeling the patient on to the adjacent balcony. The Morland Hall Cot at the Treloar Hospital is maintained by contributions of patients at the clinics and their friends, and as a result of the fête a sum of over £50 has been sent to the Treloar Hospital.

The issue of the *Revue de Médecine* for May, which is devoted to rheumatism, contains articles by F. Bezancou and M. P. Weil on degenerative hypertrophic osteoarthritis, rheumatism and climate by M. P. Weil, and chronic rheumatism in 1933 by F. Françon.

A supplement to the June issue of *La Pediatria* is dedicated to Professor Rocca Jemma, who occupies the chair of children's disease at Naples, on the occasion of his thirty years' professional activity. It contains a biographical note, a bibliography of his 137 contributions to literature, congratulations from paediatricists of all countries, abstracts from his *Festschrift*, and an account of a ceremony held in his honour.

Dr. James Somerville McLester, professor of medicine in the University of Alabama School of Medicine and an authority on diseases of nutrition, has been elected president of the American Medical Association.

The Italian Central Council of the Campaign against Cancer has offered ten prizes of 500 lire each to practitioners who have reported the largest number of cancers still in the curable stage between July 1st, 1933, and June 30th, 1934.

On June 13th the honorary degree of Doctor of Science was conferred upon Sir Henry Wellcome, LL.D., F.R.S., by the University of Marquette, Wisconsin, U.S.A.

Mr. Ingleby Oddie, the Central London coroner, has appointed Dr. Hervey Wyatt as his deputy in place of the late Dr. Idris Evans, and Dr. Reginald Hearn as assistant deputy.

The widow of the late Professor Recasens, the eminent gynaecologist and dean of the Medical Faculty of Madrid, who died of cancer, has recently founded a prize for the best essay on the disease.

The Belgian State School for Tropical Medicine has been transferred from Brussels to Antwerp, and has changed its title to the Prince Leopold Institute for Tropical Medicine.

A severe epidemic of rabies has broken out in the southern and western districts of Estonia. Three hundred persons who have been bitten by mad dogs or cats have been sent to the Pasteur Institute at Dorpat for treatment. The authorities have ordered that all the mad dogs and cats—700 in number—should be shot.

From January 1st to May 1st 1,020 cases of typhus were notified in Rumania, with 112 deaths; in Yugoslavia 882 cases, with sixty-four deaths; in Bulgaria 121 cases, with eleven deaths; and in Czechoslovakia twenty-four cases, with one death.

The Council of the University of Paris has conferred the title of doctor *honoris causa* on Dr. A. Eiselsberg, eminent professor of surgery in the Vienna faculty of medicine.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Home for Child with Eczema

"M.R.C.P." writes: Could anyone recommend a convalescent home or suchlike (preferably near Birmingham) suitable for a boy, aged 4, who has eczema but is otherwise healthy?

Drug Rash

"J. D." writes: I would be very glad of any suggestions from your readers for the treatment of the following case. The patient is a man, aged 60, who, for the past thirty years, has broken out into a generalized, intensely irritant, scarlatiniform rash on the administration of any kind of medicine whatsoever. The rash is followed by desquamation in three or four days. He is now suffering from inoperable carcinoma of the colon, and prefers the pain of his condition to the agony involved by the administration of an opiate.

Results of Operation for Elephantiasis

Dr. J. F. Knox (Rochdale) writes in reply to "I. S. Q." (June 30th, p. 1195): As to end-results of the Kondoleon operation for elephantoid condition of the lower extremities, I can report good results in a case operated on in 1929 by Dr. W. H. Bateman and myself. The leg still fluctuates slightly in size, but is substantially the same. The greatest circumference was just above the ankle, and was 34 inches. Since the series of operations it has remained at 14 inches. There has been no further diminution in the size of the leg from drainage of lymph through the windows in the deep fascia. The principal mass in our case was below the knee, and the reduction in bulk was obtained by carefully planning the incisions and the removal of huge masses of fibrous tissue. The case was of long standing. A useful account of the operation will be found in *Keen's Surgery* (vol. viii, p. 643), and an instructive report of cases in the *British Journal of Surgery* (vol. ix, p. 112).

House Flies

Dr. ROBERT A. WELSH (Felton, Northumberland) writes in reply to "G. L." (July 7th, p. 47): I have a sun-room that every now and then swarms with flies and wasps, and my wife sprays Keating's insect powder along the window frames, etc., and within an hour there is not a living fly or insect in the place—they are lying dead everywhere, and there is peace until another swarm comes along; this, however, gives us a long interval of freedom. It is a new structure—there are no old wooden frames or joints to harbour breeding places.

Income Tax

Cash Basis—In-coming Partner

"CURIOUS" took over as from July 1st, 1930, the half share of a retiring partner, including his share of outstanding book debts. As from the same date he took another

practitioner into partnership on a half-share basis. The practice has continued to be assessed on the basis of cash receipts, and, of course, all receipts have had to be brought in, including those purchased by "Curious." How should the tax assessed be divided as between the two present partners?

* On the basis that as from July 1st, 1930, they have an equal share in the gross assessments. It has to be borne in mind that the bringing in of the whole of the cash received is done merely to ensure that the tax assessed in respect of the income of the year to April 5th, 1932, shall reflect a full year's income—which it would not do if some of the cash received in the year to December 31st, 1930, were excluded. Of course, if "Curious" and his partner agree on some other basis of division that is a matter for themselves, but if the former pays a special share of the tax because he is taking the result of the old bookings, then the latter should ultimately pay to "Curious" tax on the amount of his share of the outstanding debts when the partnership terminates.

Rates of Depreciation

"X Y Z" inquires what are the rates applicable to various items.

* (1) Light therapy apparatus—no clearly recognized rate; probably 10 per cent. will be given, and the net loss on replacement should be claimed by way of "obsolescence." (2) Motor car—20 per cent., of which apparently one-quarter will be regarded as applicable to private use. (3) Microscope and consulting room furniture—probably the depreciation allowance will be refused, in which case the expense of replacement should be claimed as and when incurred.

Car Transactions—Hire Purchase

"T. F." entered into a partnership in October, 1932, and the first accounts will be prepared up to December 31st, 1933. During that period he bought one car for £95 and sold it for £95; a second car for £185 and sold it for £245; and a third car for £325. Since January 1st, 1934, he has sold that car for £215, bought a fourth car for £285, sold it for the same amount, and bought a fifth car for £435. What should he claim?

* Wear and tear (or depreciation) claims are made as for the various years of assessment. In the rather unusual circumstances we advise "T. F." to claim:

(a) For the period October, 1932, to April 5th, 1933, £95 at 20 per cent. for five months	8
(b) For the year to April 5th, 1934:	
(1) (£95 - £8) = £87 at 20 per cent. for three months	4
(2) £185 at 20 per cent. for one month	3
(3) £325 at 20 per cent. for eight months	43
	£50
(c) For the year to April 5th, 1935:	
(1) (£325 - £43) = £282 at 20 per cent. for two months	9
(2) £435 at 20 per cent. for ten months	72
	£81

The difference between the cash prices of the various cars and the aggregate of the hire-purchase payments can be treated as expenses of the periods in which they were made.

Payment of Annuity under Agreement

"J. F. B." signed an agreement in 1929 to pay £25 a year to a relative "in consideration of natural love and affection," and has since paid the annuity under deduction of tax. The relative claimed repayment of the tax after the document had been exhibited to the local inspector of taxes. The claim is dealt with now by another office, and the other inspector states that the undertaking should have been by deed under seal, and is requesting the tax repaid to be refunded. What is the legal position?

* In all the circumstances we doubt whether the second inspector has the right to reopen the past years, even if he is right on the merits; and this is by no means clear, seeing that there was "good consideration" (though not "valuable consideration") for the agreement. We advise our correspondent to write to the Secretary, Board of Inland Revenue, Somerset House, quoting the facts and asking for an official ruling in the matter. If that should be favourable the necessity for considering further steps will not arise.

LETTERS, NOTES, ETC.

Hypochondriasis

Dr. SYDNEY PERN (Melbourne, Australia) writes: It is with a good deal of astonishment that I read Dr. Robert Hutchison's article on hypochondriasis, in the *Journal* of March 3rd (p. 365). He states: "I am convinced that the amount of early disease which could be detected by periodic examination is negligible, and that it would be more than offset by the amount of nosophobia that would be created by it. And as regards prevention, surely every doctor worth his salt has always been doing all he can to prevent disease. . . . Of course, if the practitioner had a larger share in the public health services he could do more in the way of prevention, but that line of approach is often closed to him." Whilst agreeing with a good deal that Dr. Hutchison has to say about hypochondriasis, I do not in any way agree that periodic examination is going to aggravate the condition, as often as not it is the result of pathological conditions undiagnosed by the medical man. At the present time we are aware that a big proportion of the diseases we are called upon to treat to-day are the result of oral and nasal infections, and long before these diseases are severe enough to warrant calling in a medical man damage has been done to various tissues and organs of the body. Because a man has a positive Wassermann reaction does not debar him from treatment, even if he has no symptoms whatever. The average man is totally unaware of pathological changes taking place in his kidneys or his arteries until they are well advanced. Periodic examination is going to prevent all these types of diseases developing, because when we find pyorrhoea or infected tonsils we must know that it is impossible to have them without detriment to the tissues, and that although there is apparently no suggestion of disease it must be there in its incipient stages. Medical men worth their salt will always help their patients to the best of their knowledge, but to many the facts as stated here are not so patent as to the writer. The amount of prevention of disease within the hands of the general practitioner is greatly in excess of that in the hands of the health officers. We are now living in an age when it is our duty to give as much publicity as possible to the causation of disease, as by doing so we shall prevent gross damage being done to organs and be able to tackle it in an early stage or prevent its occurrence all together. If, by any chance, a few hypochondriacs are created the gain to the majority will far outweigh the harm to the few.

Weil's Disease among Sewer Workers

Dr. F. WILLIAM COCK (Appledore, Kent) writes with reference to the leading article in last week's issue (p. 27): In the *British Medical Journal* for July 31st, 1897, you quoted from a report on the overcrowded burial places in Liverpool. It was mentioned that one of the men employed in repairing a sewer died apparently from the effects of his occupation. It was suggested that a very foul jelly-like substance attached to the wall of the sewer where that lay alongside the burial ground might have had something to do with this. ? Spirochaeta.

Disclaimer

Dr. HENRY YELLOWEES (London, W.1) writes: My attention has to-day been drawn to an article in the *Empire News*, which refers to me by name and prints my photograph. I was entirely ignorant of the whole matter till to-day (July 10th), nor have I the slightest knowledge as to how the material for the article, or the photograph, were obtained.

From July 14th the telephone number of the head office of Burroughs Wellcome and Co. in London will be Central 4,000.

Ilford Limited (London) have sent us a pamphlet entitled *Photography as an Aid to Scientific Work*. Copies may be obtained post free on application. Information contained therein should prove useful to those wishing to know what type of plate, etc., is required for any particular scientific purpose.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 49, 50, 51, 52, 53, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 56 and 57.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 36.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JULY 21st, 1934

SYPHILIS IN PRACTICE*

BY

HENRY MACCORMAC, C.B.E., M.D., F.R.C.P.
PHYSICIAN FOR DISEASES OF THE SKIN, MIDDLESEX HOSPITAL

Is syphilis uncommon in general practice? I have often asked this question, and have as often been assured that syphilis only accounts for a very small part of the practitioner's miscellaneous occupation. This does not seem to agree with hospital experience, or at least with the experience gained in a venereal clinic. Thus in 1,000 consecutive cases taken from the department for syphilis at the Middlesex Hospital I find the distribution of the disease as follows:

Primary ...	133	Syphilis of the eye ...	55
Secondary ...	172	Syphilis of the throat ...	112
Neurosyphilis ...	130	Miscellaneous ...	342
Cardiovascular syphilis ...	42		
Visceral ...	14		1,000

Out of these 1,000 patients, who may be considered a representative sample of the syphilized population, only 305, or 30.5 per cent., belong to the early or communicable stage. This may provide the explanation to a common, but I believe an erroneous, impression, for when I have further questioned my informants I find that by syphilis they usually mean and think of the early stages of the disease, whereas the term has, of course, a very much wider significance. This is partly because the early period has been given special prominence in the propaganda against the disease, and partly because the later developments are observed in special departments, and thus come to be related to diseases of the bone, eye, ear, or nervous system rather than to syphilis as a whole.

There are thus grounds for believing that the syphilitic taint is far more prevalent than is usually supposed. Nor is the disease decreasing, in spite of the efforts of the public clinics. Further, we have still to feel the effects of the syphilization of the war and the period that immediately followed.

To be prepared to recognize every form of syphilis, and to attempt to forestall or remedy all the possible consequences of infection, demands a comprehensive knowledge which is outside the scope of everyday work. The following short formula reasonably covers all the necessary ground, and provides a simple key to most of the problems likely to arise:

1. Early syphilis is communicable and curable.
2. Late syphilis is not communicable, and only cured with difficulty and in exceptional cases.

Early Syphilis is Communicable

A statement so obvious seems to need no comment. Syphilis is readily transmitted through the mucous membrane during sexual intercourse and in kissing, but apart from this the risk of infection is apparently inconsiderable. This has an important bearing on many domestic problems—for example, a recently infected individual living

in a household. Provided ordinary precautions are taken the danger to others would seem to be slight, and this is constantly confirmed by experience. While each case must be considered on its merits, the domestic servant requires special consideration, and the practitioner may have to decide whether he should disclose to the head or the household facts which have come to his knowledge in the exercise of his profession. The obligation to secrecy allows of exceptions: the circumstances related below would seem to justify extreme measures. A children's nurse was found to be suffering from a highly infective form of syphilis. Her lips and mouth presented numerous mucous patches. Although the nature of the disease and its possible consequences to her charges were clearly explained to her, she refused to leave her situation voluntarily. Such an occasion would no doubt be regarded in law as privileged. According to Dixon Mann and Brend[†] a privileged communication is one which is prevented from being defamatory and actionable by circumstances rebutting the existence of malice: there must be an interest to protect or a duty to perform. Fortunately, the circumstances calling for such measures can only rarely arise: further, it is to be remembered that special privileges in this respect are conferred by law upon patients attending the public venereal clinics.

Early Syphilis is Curable

When we speak of cure it is necessary to define the sense in which we use the word. Here it is taken in its literal meaning. There are some authorities who believe it is still too early to judge of the results of modern treatment. On the other hand, it is to be remembered that in the case of syphilis we are in possession of specific remedies—the arsenicals, mercury, and bismuth—and a delicate specific test, the Wassermann reaction, which permit of a precision in treatment and in testing the results of treatment that is unique in medicine. We have therefore substantial grounds for presuming cure, provided that the patient has completed a standard form of treatment, and provided also a sequence of negative blood tests have been observed over a sufficient period.

In the early stages of the disease our object is to cure the patient: that is a personal service to the individual. Incidentally a contribution is made to the public health by excluding a potential source of infection. With such objects in view the most vigorous intensive treatment is justified. On the introduction of the arsenical remedies it was thought that no more than a short course was required: this opinion has long been abandoned.

In 1913 the late Sir Malcolm Morris and I[‡] advocated salvarsan followed by mercury, continued with intermissions for two years, and I would further add that a full two years is desirable in all forms of the early disease, whether primary or secondary, because in both

* Based on a lecture given to the Fellowship Division of the British Medical Association.

cases we are dealing with a generalized infection which merits similar intensive treatment pushed to the limit of tolerance of the patient. A distinction is sometimes made between primary syphilis with negative Wassermann reaction and primary syphilis with positive Wassermann reaction. This is demonstrably unsound, for if the blood is tested at regular intervals while treatment is in progress it becomes evident that both conform to the same pattern, as Kennaway and I² have shown. The intensive treatment should begin with an arsenical compound, preferably of the 914 type because of its convenience.

In the scheme originally adopted at Middlesex Hospital and continued for some years, a first intravenous injection of 0.6 gram N.A.B. was followed by nine further injections each of 0.9 gram at weekly intervals, for both men and women. This vigorous policy proved completely satisfactory. There were no calamities; even the minor inconveniences of arsenical medication were rare, and jaundice was almost unknown. Later, when the first dose was reduced to 0.3 gram, followed by nine injections of 0.6 gram, jaundice became much more common, which may indicate that so-called arsenical jaundice is, in some cases at least, syphilitic. After the preliminary arsenic, mercury in series of twelve intramuscular injections, one each week, with a rest of one month between each course, completed the two-year treatment. For some time past bismuth used in the same way has replaced mercury. An additional arsenical course following the first mercury or bismuth series may be considered necessary where the Wassermann response lags, or for other reasons.

What results can be expected from intensive treatment? To test this some 1,800 consecutive cases have been reviewed. Out of this number only 121 proved suitable for analysis; the remainder were examples of nerve, ocular, congenital, or cardiovascular syphilis, etc., or, if in the early stages, had defaulted. These 121 cases—thirty-five primary and eighty-six secondary—have been brought together in tables in which only those with at least two years' observation have been included. In every case the diagnosis has been verified either by a preliminary Wassermann reaction or by the presence of *S. pallida* in the primary sore. A word may be said concerning the subsequent blood examinations: the figures given in the column headed "subsequent W.R.: blood" summarize the form of the reaction throughout the whole period of observation, representing, in most cases, a large number of separate tests.

The investigation of the cerebro-spinal fluid, shown in the adjoining column, was invariably carried out shortly after the conclusion of treatment. An earlier examination may be misleading, because, as is now well known, in all forms of recent syphilitic infection involvement of the central nervous system as shown by the changes in the cerebro-spinal fluid is relatively common, the central nervous system participating in the general infection. This accepted fact, taken with the findings shown in the tables (examination of the cerebro-spinal fluid), permits of two conclusions: first, that the spirochaetes in the central nervous system can be, and are, reached and destroyed by intramuscular and intravenous treatment, and secondly, as one is entitled to infer from the above, that the specialized technique which claims to influence syphilis of the central nervous system by introducing therapeutic substances directly into the cerebro-spinal fluid is unnecessary and presumably much less efficacious than the intramuscular and intravenous routes. Further, in early syphilis the blood reactions in themselves afford a very reliable indication of the condition of, and result of treatment in, the central nervous system. If they have followed a favourable course during standard treatment it will then

be found that the cerebro-spinal fluid is negative to all tests if examined at the proper time—that is, three months after the full course has been completed.

Taking the primary cases first (Table I), twenty-one out of the total thirty-five may be considered as cured—that is, 60 per cent. In contrast to this, out of eighty-six secondary cases approximately 81 per cent. have been cured (Table II). These figures imply, contrary to the generally accepted view, that the chance of cure is greater in secondary than in primary disease. The evolution of an arsenic-resistant type of spirochaete, as suggested by Drake and Thomson,⁴ may explain this paradox. This postulates a type of spirochaete which has learned to accommodate itself to the arsenicals but not to the natural antibodies formed in the secondary stage. If the arsenicals are used very early these natural antistances may be prevented from developing. In this connexion it is interesting to recall the investigations of Bruusgaard⁵ into the after-history of Caesar Boeck's patients. Boeck held and

taught that mercury and iodides interfered with nature's efforts to eradicate syphilis, and he only used drugs where he considered the body had failed to react. Bruusgaard has been able to trace the after-history and condition of many of these untreated patients, and has shown that a considerable proportion of them recovered completely. It is clear from this that the natural antisyphilitic substances are not negligible, and if they are allowed to develop, as in the secondary stage, have then an important therapeutic action, which may explain the better results obtained in secondary syphilis. The idea of an interference with the natural protective substances by specific arsenicals is today represented in the alleged increase in neurosyphilis attributed to arsenical treatment. Certain observations of the late Professor George M. Robertson* bear upon this question. In the seventh Maudsley Lectures he called attention to the sudden fall, in 1919, in the number of deaths from general paralysis of the insane, a decrease which he said was maintained. He reasoned as follows: "The symptoms of general paralysis do not occur with any frequency until seven years after infection, and the patient

usually lives two years after the disease has declared itself. Therefore nine years before 1919 something had happened to account for the observed fall in the accurately recorded death rate of this disease. In 1910, the year in question, Ehrlich introduced "606." This does not accord with the theory that early intensive treatment increases the vulnerability of the central nervous system, nor does the routine examination of the cerebro-spinal fluid in adequately treated early cases favour this hypothesis.

Cure may be presumed where the blood Wassermann reaction has become negative after the first course of treatment and has remained negative subsequently for two years. This has at least the merit of a working proposition. Discrepancies are, of course, met with, as in the following exceptional case:

In 1920 a woman, aged 28, attended the clinic with a primary sore on the lip and a secondary rash (No. 1163). Blood Wassermann reaction and spirochaete test both positive. She was treated for two years and attended regularly for observation up to July, 1926. The blood reactions followed a favourable course and remained constantly negative in the succeeding years up to July, 1926. The cerebro-spinal fluid was also negative. In November, 1926, she contemplated marriage, and her blood was again tested; this and a confirmatory Wassermann taken a week later both proved strongly positive. For six years she had satisfied every criterion: then when it seemed she was entitled to be considered cured, a serum relapse developed suddenly and unexpectedly.

Some of the cases referred to in the tables merit additional details. While primary syphilis sometimes provides the most resistant and most disappointing forms of the early disease (see 1,145, 1,168, 1,509, 1,656, 1,682, 1,766, 1,885, 1,942, 2,350) it is, on the other hand, generally recognized that cure, or apparent cure, may follow courses of treatment so short as to seem on theoretical grounds at least totally inadequate. In a similar way in secondary syphilis cure, or apparent cure, can sometimes be obtained by forms of treatment which fall far short of the two-year standard. Thus a proportion of those recorded as cured received no more than one year of treatment and in exceptional cases even less. This raises the question whether the two-year standard is not unduly severe. The experience gained from the defaulters from my own and from other clinics goes to show how unsatisfactory inadequate treatment usually is and how often it fails, for serum or clinical relapse may develop in the inadequately treated even after a latent period of so many years that cure has been reasonably assumed, as in the following instance:

No. 805 attended with secondary syphilis from November, 1919, to June, 1920. He was given ten intravenous injections of N.A.B. (total 8.7 grams) and twenty-six intramuscular injections of mercury. His blood Wassermann reaction was negative at the end of this course of treatment, and further negative tests are recorded in November, 1920, June, 1921, November, 1921, May, 1922, July, 1923, and October, 1927. His circumstances precluded an examination of the cerebro-spinal fluid. This patient was seen again in 1934, and it was found that he had developed *tabes dorsalis*. This goes to show that a long series of negative blood tests is only reliable evidence of cure when a full standard treatment has been completed.

To follow up patients is never easy, and although every encouragement is held out to the patient with syphilis to report at regular intervals and keep under observation, sooner or later he or she disappears. Nevertheless, it has been possible to trace and review the present state of two, both early defaulters, whose treatment was meagre, who returned at intervals for observation.

Thus 1,096 was only treated for three months (8.7 grams N.A.B. and seven mercury injections) in 1920; blood Wassermann reaction negative in 1923 and 1927. Recently (January, 1934) a careful general examination failed to reveal any

organic disease, and the blood Wassermann reaction was negative.

No. 1,459, treated in 1921 (sore on lip and rash), received seven injections N.A.B. (total 6 grams) with concurrent mercury. She then developed severe arsenical dermatitis, afterwards refusing further antisyphilitic treatment. She was seen again in 1923, 1927, and in January, 1934. On all these occasions the blood Wassermann reaction was negative. Her general health has remained excellent. She declines lumbar puncture: so far, however, as can be ascertained her nervous system is normal.

These two patients have been classified as cured with some misgivings. If this happy end has been achieved they may be counted among the fortunate exceptions who have done very little to merit the result.

Late Syphilis is Not Communicable

A positive Wassermann reaction does not always mean potential or actual infectivity. It should be interpreted in relation to the duration of the disease and the sex of the individual. Thus a man who marries ten or fifteen years after infection need not necessarily fear that his children will be tainted, even where his Wassermann reaction remains positive. Congenital syphilis is transmitted through an infected mother. In such circumstances the man's disease, owing to its duration, is usually no longer communicable: his wife escapes contamination, and therefore the link required to transmit his disease to his offspring is wanting. An exception may be given:

A young man received twenty injections of arsenical compound for secondary syphilis and subsequently an intermittent and incomplete treatment with mercury. Four years later he developed pityriasis rosea, and in view of his history a blood test was made at his own request, which proved positive. Subsequently further interrupted treatment was carried out, but again in intermittent form, and he remained uncured. Six years after the original infection he married, and eighteen months later his wife developed syphilis. This case has many exceptional features, and is unique in my experience.

The sex of the individual with old-standing syphilis has an important aspect. The woman with late syphilis, although her Wassermann reaction is positive, may not be able to infect her husband; nevertheless, during the child-bearing period she remains capable of transmitting the disease to her children. All the risks of congenital syphilis continue to be present; miscarriage may occur, or the child may survive to develop in infancy or later one of the many manifestations of the congenital taint. Fortunately there is a remedy for this state of affairs; if the latent syphilis is detected, and if the expectant mother is adequately treated during her pregnancy, the child escapes contamination. Preventive measures of this kind constitute the best, and indeed the only, satisfactory method of frustrating congenital disease, and this applies to early as well as latent syphilis in the mother. To this there would appear to be one exception: if the cerebro-spinal fluid of the mother is positive, intensive treatment may fail to secure the desired object, as pointed out by Miss Gladys Sandes.⁷ As *tabes* and general paralysis are, however, comparatively rare in syphilized women, only 0.5 per cent. developing such conditions as contrasted with 3 to 5 per cent. in men, this disturbing factor is not considerable.

Those who are historically minded will observe the bearing of these facts upon the medical history of Henry VIII. Mr. Frederick Chamberlin,⁸ Dr. MacLaurin,⁹ and Mr. Macleod Yearsley¹⁰ have all found it difficult to reconcile Henry's presumed syphilis with the condition of his later children. This is not surprising if we examine the facts in the light of the statement above.

In 1509, at the age of 19 years, Henry was called to the throne, and in the same year married Catherine of Aragon.

At this period he must have been infected and have infected his wife, for from 1510 to 1518 there are a series of stillborn children or children who only survived birth. In the middle of this series, in 1516, Mary was born. She suffered from ozaena, severe headaches, and defective vision, possibly from interstitial keratitis (Macleod Yearsley). The obstetric record of Catherine of Aragon is typical of an untreated syphilitized woman infected at marriage. The condition of the other children present no bar to the hypothesis of syphilis in the King, their father. Ten years after infection Henry had a child by Elizabeth Blunt, called the Duke of Richmond. Queen Elizabeth, born still later, was the daughter of Anne Boleyn; and Henry's last child, Edward VI, born in 1537, was the son of his third wife, Jane Seymour.

Old-standing syphilis is not communicable; therefore all the mothers of the later children, and consequently their children, escaped contamination. Queen Mary alone can be considered to have suffered from congenital disease.

Late Syphilis is only Cured with Difficulty and in Exceptional Cases

Some years ago I should have been inclined to regard the prospect of cure in late syphilis as uncertain, or at least improbable. Since the introduction of bismuth therapy there has been reason to modify this opinion. Bismuth is used in early syphilis for its convenience, and especially for its painlessness; it is then as good as mercury. But it is in late syphilis that bismuth has its special application, and since its general employment the chance of curing or arresting nearly all forms of long-standing disease has been notably improved. In passing, it may be pointed out that the results of the arsenic-mercury combination in early disease, as seen in the tables, surpass those obtained where bismuth has been given. This is, however, a matter of a chance sample, and does not therefore represent the actual facts.

Late or chronic syphilis may be conveniently considered in three groups: (a) cardiovascular, nerve and visceral; (b) cutaneous; and (c) serum-positive cases without other definite signs. While the form and duration of treatment is or may be very different in each group, it cannot be too strongly insisted upon that each case merits that individual consideration which the state of the patient and the nature of the symptoms demand.

In the first group the intention of treatment is to arrest the progress of disease and to prevent further damage to an organ or tissue already impaired. A greater or lesser degree of organic disease is present, and it is therefore neither desirable, nor as a rule safe, to impose upon such a patient the kind of intensive treatment which is readily tolerated by a young, robust adult with early disease. Nevertheless some form of prolonged treatment is, as a rule, necessary: the difficulty can be overcome by lengthening the intervals of rest between each course up to three or even six months. As has been indicated above, intramuscular bismuth constitutes the principal agent of attack, and its action can be supplemented by a course of five to ten intravenous arsenicals, either at the beginning of treatment, or at a later stage, if there should seem to be a risk of a focal reaction in a vital organ before protection from such a reaction has been obtained by a preliminary series of the more moderate bismuth or mercury. This applies especially to cardiovascular disease, where, indeed, the administration of any form of the arsenical substance may be considered undesirable. In intracranial gummata, bismuth should precede neosalvarsan for the same reason. The progress of the patient can be judged by the improvement in symptoms or by the diminishing strength of the Wassermann reaction in units, and for this purpose a series of tests must be made; the "strength" of a single test has, of course, no clinical significance in any form of syphilis, as it bears no relationship to the severity of the infection

or the degree of the disease. In *tabes dorsalis* an indication of this kind may not be available, for it is well known that the Wassermann reaction may die out in the blood and in the cerebro-spinal fluid even in progressive forms of *tabes*. With this exception a sustained fall in the Wassermann reaction units holds out a prospect of cure under continued treatment—that is, a prospect of the elimination of the infective agent which has caused the pathological changes, but not, of course, a return to a normal condition of the diseased organ or system, the functioning of which, however, can be, and usually is, improved, as shown by the favourable modification of the symptoms which its dysfunction has brought about. While meningo-vascular syphilis is directly influenced through the blood stream by the remedies injected into the muscle or vein, it is held that the choroid plexus, acting as a barrier between the blood stream and cerebro-spinal fluid, prevents the arsenical and presumably the other blood-borne therapeutic substances from entering the cerebro-spinal fluid and influencing the parenchyma, and this criticism applies in particular to the treatment of *tabes*. Since we know little of the nature of the specific antisubstances which are formed when arsenic or mercury or bismuth is introduced into the body, we have no means of testing whether they do or do not pass from the blood stream into the cerebro-spinal fluid following intramuscular or intravenous injections. We have, however, as has already been pointed out, the clinical and serological evidence of their curative action, when so administered, on the infection of the central nervous system in early syphilis, which implies that in *tabes* they may be similarly effective when similarly used.

Late Cutaneous Syphilis

The development of a late cutaneous lesion, or a gumma arising in the subcutaneous area, is the most fortunate event that can happen to the individual with latent syphilis, because the appearance of a lesion or lesions of this kind is an almost certain guarantee that the central nervous system is, and will remain, unaffected. The recognition of the indemnity of the central nervous system in these circumstances has even suggested that two strains of spirochaete exist, one with a special affinity for the skin, the other for the nervous elements. Clinical experience is destructive to this theory. Thus on a number of occasions I have observed a man with *tabes* and his wife with cutaneous gummata, or the circumstances reversed. The reaction to the pathogenic agent thus dwells in the individual, since the same strain of spirochaete can be presumed to have infected both parties. Even more convincing are those very rare cases where *tabes* and skin gummata coexist, as in the following (No. 968).

This patient, a man aged 51 years, when first seen in 1920 had acquired syphilis twenty years earlier, when he was treated with mercury pills for eighteen months. In addition to *tabes dorsalis*, severe lightning pains, and a perforating ulcer, he presented over the left leg extensive superficial scarring, marking the site of a late cutaneous syphilide.

Skin gummata, superficial or deep, provide the most convincing example of the efficacy of the arsenicals in the rapidity and completeness with which even extensive areas heal and cicatrize, and this satisfactory result can be obtained by relatively few injections. In consideration of this, and in consideration of the prospect of a similarly responsive reaction should a relapse take place, it would seem that any form of prolonged treatment may be unnecessary, especially as we can rely upon the integrity of the central nervous system in such cases. The possibility of disease in other regions should not be forgotten, the buccal mucous membrane in particular. In long-

standing syphilis in men who smoke, syphilitic leucoplakia of the tongue is far from uncommon. Since this is so often the precursor of cancer of the tongue it provides a factor which must be taken into account should it be discovered.

Serum-positive Cases without Other Signs

The accidental discovery of a positive blood Wassermann reaction in an individual apparently healthy is met with from time to time. The test may have been made from caprice or as a part of a routine examination or for some other reason, and stands in quite a different category from those cases where an examination has been carried out to confirm the diagnosis of some suspected syphilitic lesion. There are undoubtedly individuals who enjoy good health and live to an advanced age, notwithstanding a positive blood Wassermann reaction: in itself, therefore, this is not an unconditional demand for treatment. A complete general examination should, of course, be carried out, including the cerebro-spinal fluid. If, apart from the blood reaction, nothing abnormal is discovered, should the patient be treated or should nothing be done? The decision turns upon the patient's age: in a young individual it would seem prudent to endeavour to bring about a cure, a procedure which will probably be lengthy and tedious, and may end in complete failure. In an elderly man or woman a negative policy will generally be decided upon; assuming an infection in early life the individual in question has passed safely through the period of greatest risk, and it is now unlikely that any of the late manifestations will develop.

Syphilis has been called the great imitator: it might equally be called the great deceiver. Its effects extend into every domain and every branch of medicine and surgery in so many different patterns and degrees as to be outside the competence of any one individual to recognize and discriminate in all its forms. In a different case stand the general principles which co-ordinate syphilis as a single disease, of which the various clinical manifestations are not isolated phenomena, but rather separate links in a complete chain.

At a meeting, in May in Paris, of the executive committee of the International Organization for the Campaign against Trachoma, it was decided to provide financial assistance for an investigator to study the aetiology of trachoma in a laboratory in a country where this disease was prevalent. A conference will be held in Budapest next spring on prophylaxis; the opening speakers will be Mr. A. F. MacCallan, F.R.C.S., and Drs. Myashita of Japan, Zachert of Poland, Tewfik of Egypt, and Jitta of Holland. The joint conference last May of this organization and the International Association for the Prevention of Blindness gave careful consideration to the question of trachoma in colonial settlements and in Southern Europe. M. Morax opened a discussion on the part played by the gonococcus in tropical countries.

RHEUMATISM AND ITS RELATION TO ARTERIAL DISEASE AND PERIARTERITIS NODOSA

BY

A. VICTOR NEALE, M.D., M.R.C.P.

AND

ALLAN G. W. WHITFIELD, M.B., CH.B.

QUEEN'S HOSPITAL, BIRMINGHAM

(With Special Plate)

It will be seen that in the above title there is a linking together of a manifestly common disease with a clinically rare disorder. The principal purpose of this paper is, however, to bring forward observations on some of the recognized manifestations of rheumatic disease as affecting the arterial system, with special regard to recorded instances and a presently observed case of affection of the visceral arteries in rheumatism.

Extent of Body Lesions in Rheumatic Disease

In 1904 Aschoff established the now well-known microscopical tissue changes in rheumatic disease, and since that time it has been common parlance to refer to the Aschoff tissue or nodes in affected areas, more especially in the ventricular myocardium. Later investigators have recorded their findings of Aschoff tissue reaction in other parts of the circulatory system. Klotz noted such effects in the aorta, and MacCallum reported his researches into rheumatic lesions in the auricular musculature. Pappenheimer also carefully investigated the subject, and noted manifestations of the Aschoff type in the cardiac muscle and various parts of the arterial system. Perry, Davis, and Schlesinger, in a recent paper entitled "Thrombophlebitis in Acute Rheumatism," review the literature on the subject of rheumatism attacking the veins, and report three cases of venous thrombosis occurring during acute rheumatism. They consider that though congestive cardiac failure may play a part in some of these cases, there is such a condition as rheumatic thrombophlebitis, and in one of their cases demonstrated Aschoff tissue in the wall of a thrombosed vein. Certainly cases are recorded of thrombophlebitis occurring during chorea in the absence of any clinical cardiac lesion.

It is thus evident that since Aschoff's original discovery much attention has been directed, both in the pathological and in the clinical aspects, towards the extent of the lesions in the body of a person who is suffering from rheumatism. Clinicians who are in close contact with large numbers of cases of the disease continually recognize the wide variety of clinical symptoms and signs that may be presented, and the diversity in duration, type, extent, and prognostic features of the affection. That rheumatic disease is a general infection (or perhaps to meet the views of some authorities, an infection having bacterial, toxic, or allergic generalized effects), possessing actual or potential capacity to damage a wide variety of structures in the body, cannot be doubted. Since Aschoff's publication it is correct to say that cardiac lesions (frequently the most important, however) are but local manifestations of a general disease.

Arterial Disease in Acute Rheumatism

In an article by A. F. Bernard Shaw some interesting general observations are made concerning arterial disease in acute rheumatism. Rheumatic valvular disease is considered by him to arise as an intrinsic valvulitis in accordance with a vascular arrangement in the particular

valves of the heart. He further considers that valvulitis precedes endocarditis, and that probably the latter cannot develop until the inflammatory process has permeated the valve leaflet as far as the line of closure. In other words, the rheumatic lesion extends in the valve tissue via the local vascular mechanisms. This view of the origin of valvular lesions in rheumatism has gained many supporters. The same author outlines the extent of vascular lesions present in a girl, aged 15, who suffered from severe rheumatic fever. The tissue changes of the disease were found in the pulmonary artery, ascending and descending aorta (medial and adventitial coats), coeliac axis, visceral pericardium, both auricular walls, pulmonary valve, tricuspid valve, diaphragm (perivascular and musculo-tendinous portion), and perivascular areas in the tonsils.

Fraser discusses and illustrates the occurrence of lesions in the lymphoid tissues of the pharynx and tonsil in acute rheumatic disease. Aschoff tissue was readily detected by him in the perivascular tissue, and although the small arterioles were not involved, definite intimal proliferative reactions were seen in the medium-sized vessels. The extent to which arterial disease may occur unsuspectedly is well illustrated in a case recorded by McMichael. A young child suffered from a toxic erythema with a pyrexial illness, and a gradual progression to extreme prostration occurred. A subacute infective process of unknown nature was present (luetic disease being definitely excluded). Pathological examination revealed thickening of the coronary arteries, which appeared prominent and opaquely white, and felt like dense fibrous cords, and which, on section, showed narrowed lumen with associated fibrotic myocardial changes; microscopically, obliterative end-arterial disease was seen in the heart wall, kidney, and spleen.

That rheumatic disease of the aorta may be of very serious import is exemplified by personal observation of two instances of rupture of the ascending portion of this great vessel during active rheumatic disease in the heart and elsewhere.

In one case a youth, aged 18, while walking briskly across a field, suddenly collapsed. On examination of his medical record it was found that he had recently been recognized to be suffering from rheumatic fever, and had been advised to rest. The necropsy revealed active valvular and myocardial rheumatism, and a remarkable transverse irregular fissure in the ascending aorta one inch above the valves; also blood had escaped into the pericardium. Close examination of the local aortic tissue showed recent softening; microscopically a diffuse Aschoff reaction was seen. In the other case, almost exactly similar clinical and pathological changes were observed; in fact, the youth was admitted to hospital because of severe rheumatic fever, and collapse occurred quite suddenly, while he was under ward observation, from rupture of an aortic fissure.

It is with special reference, however, to rheumatism and periarteritis nodosa that attention is drawn in this paper. The relation of such to bacterial infection has long been suspected, and modern views hold strongly to the streptococcal agency in rheumatic disease. That infection and toxæmia from a similar organism may, on occasion, produce in the same patient extensive cardiac and visceral arterial disease will be indicated later.

Herlitz, in a recent review of several cases of periarteritis nodosa, notes its possible occurrence in association with a variety of infective processes, more especially, however, in streptococcal infection. This author considers that the same organism may cause rheumatism and periarteritis in the same patient, but that such peculiar association is a variable one, and is possibly connected with some special modification in the recipient soil (arterial system) or in the infective micro-organism.

Age and Sex Incidence of Periarteritis Nodosa

As a matter of special interest it would be advisable to make herein some observations on the more recently recorded facts concerning periarteritis nodosa. Rothstein and Welt, in their recent paper, have extensively surveyed the problem, and much valuable information is given by them. The disease is first of great interest because of its bizarre symptomatology, which adds to the diagnostic difficulties. Periarteritis nodosa was first described by Kussmaul and Marie (1866), although instances of "innumerable aneurysms in the walls of small arteries" had previously been noted. Its incidence is higher in males, and the youngest recorded patient was 3 months and the oldest 78 years. The third decade shows the highest incidence, but twenty-one cases under 15 are reported by Rothstein and Welt.

Clinical Manifestations

The characteristics of the disease are clinically revealed as a fairly acute infection, the more usual symptoms being irregular fever, increasing weakness and loss of flesh, prostration, anaemia, tachycardia, splenomegaly, and leucocytosis. Associated with the general symptoms are certain special phenomena due to widely scattered vascular changes in the body; "rheumatic" pains due to affected arteries in the muscles; albuminuria and haematuria as an effect of closure of renal vessels and kidney infarctions; and intestinal haemorrhages or symptoms simulating colitis when the mesenteric vessels are involved. There may also be various cerebral symptoms through the disease involving the cerebral arterial system. Occasionally erythematous or even petéchiial rashes appear, and oedema (of renal type). Subcutaneous nodules have been found, representing either thickening in the wall of the blood vessels or actual small sacculated aneurysms (in which thrombosis occurs) in the arterial coats. Such nodules are described as small, firm, pea-sized masses, feeling shot-like, and lying along the course of an artery. These nodules, however, have only been detected in 20 per cent. of cases. Pain in the voluntary muscles may be a very pronounced symptom (some cases, on this account, have been suspected of trichinosis). Arthralgia may simulate rheumatism, and many cases have accompanied or followed sore throat or tonsillitis.

Variations in Clinical Syndrome

Periarteritis nodosa may, for convenience, be grouped into six general clinical types: gastro-intestinal, renal, muscular, cardiac, cerebral, and cutaneous. Any one case, however, may be a combination of the several types, since the clinical variations merely depend upon the same disease process involving arteries supplying the nerves, muscles, or particular organs affected, and the clinical syndrome will vary accordingly. Renal involvement would seem to be a special feature, since in 74 per cent. of cases haematuria has occurred. One very remarkable case reported by Bennett and Levine clinically simulated meningitis, the cerebro-spinal fluid having a high leucocyte count but no demonstrable bacteria, while pathological examination later revealed typical lesions of periarteritis nodosa widely distributed. Acute abdominal symptoms may arise and so simulate a surgical emergency; several cases are reported in the literature in which laparotomy was performed for such suspected diseases as acute appendicitis, perirenal abscess, cholecystitis, etc. In some cases in the later stages sudden collapse has occurred due to intra-abdominal haemorrhage from arterial rupture. The more serious symptoms arise as a result of thrombotic occlusions or rupture of arteries in vital areas; fatal cases due to rupture of acute arterial aneurysms in the brain, lung, intestine, liver, kidney, and pericardium have all been recorded.

Associated Aetiology of Periarteritis and Rheumatism

On considering the true aetiology of periarteritis nodosa most authors regard it as a special response to an infection, but no specific micro-organism has been recognized. The most interesting suggestion is that of its relation to the aetiology of rheumatic infection, an association which is strengthened by the frequency with which periarteritis has been accompanied by tonsillitis, arthritis, myalgia, and cutaneous rashes, etc., and also by the current views that rheumatic disease is directly associated with infection by streptococci. Rothstein and Welt have recorded a case in which lesions due to rheumatic fever and to periarteritis nodosa were both present.

ROTHSTEIN AND WELT'S CASE (Abstracted)

Boy, aged 7, no important previous disease and no previous rheumatism. Mild attack of scarlet fever followed by usual desquamation; three weeks later pyrexia and cervical adenitis. Attacks of severe cramp-like epigastric pain lasting ten to fifteen minutes; fever, enlarged cervical glands, and the pains lasted five days. Pain occurred in the foot, thumb, and groin, these pains being transient, migratory, and aching, but insufficient to limit movements. Five weeks after initial illness dyspnoea, weakness, and pallor became evident, and diagnosis of rheumatic heart disease was recorded. The temperature then noted to be 106° F., and evidence of mitral lesions present. Leucocytes 16,000 per c.mm.; blood cultures negative. Congestive cardiac failure. Pathological examination revealed rheumatic valvular disease with typical verrucose vegetations on the mitral, and to a lesser extent on the aortic, valves; Aschoff bodies in the myocardium on microscopical examination. Gross periarteritis nodosa was revealed involving the pulmonary, coronary, and renal arteries, while microscopically the arterial changes were seen also in the liver, stomach, diaphragm, suprarenal capsules, pancreas, spleen, and a branch of the external iliac artery. The authors consider this case to be an example of the "cardiovascular type of periarteritis nodosa" which "clinically seemed one of rheumatic cardiovascular disease with rapid decompensation and subsequent cardiac failure."

A personally observed case of combined rheumatic disease and extensive visceral arterial disease was carefully investigated by us, and the following descriptive data are given for consideration.

Authors' Case of Combined Rheumatic and Arterial Disease

The patient, a boy of 15, gave no history of rheumatism or of any other illness until seven weeks before admission, when he complained of pain in the back and in several of his joints; he was noticeably drowsy, on one occasion falling asleep at work. Later his speech became slurred and indistinct; he grew more and more fidgety and restless, and his gait became bad. On admission his temperature was 102.5° F., but apart from this he presented the typical picture of a severe case of rheumatic chorea. He could not keep still for a moment: his face was constantly twitching and grimacing, he had the characteristic choreic glossal movements, and his lips were bleeding where he had bitten them. His hands, when extended, showed the flexion of the wrists and the hyperextension of the metacarpo-phalangeal joints which is so invariably seen, and when gripping one's hand he writhed about in the bed as though to increase the strength of his grip, which varied in the usual manner. When he put his hands above his head he could not keep the palms facing one another, and the alteration in respiratory rhythm was very obvious. The left knee-jerk was choreic, and the skin on his elbows, heels, and shoulders was red from the rubbing brought about by his unceasing movements. The fundi were normal, and apart from the left knee-jerk the reflexes were normal. Clinically the heart was not enlarged, and the sounds were closed. The pulse was 118 and regular. There was a faint haze of albumin in the urine, but microscopically no cellular elements were seen. There were no rheumatic nodules, and the skin was dry.

DIAGNOSIS AND TREATMENT

A confident diagnosis of chorea was made, and 30 grains of sodium salicylate every four hours was prescribed. At first the patient's pyrexia seemed to respond to this therapy, but during the whole period in hospital his temperature was never normal for twenty-four hours together. The choreic movements remained as violent as ever, and he frequently complained of severe precordial pains, headaches, and limb pains, especially in the hands, for which no cause was apparent. The albuminuria persisted, but no blood was found even with the microscope. The heart remained quite normal clinically and the spleen was never palpable, but he was rapidly losing flesh and obviously going downhill. Throughout the illness the skin remained remarkably dry. Liquor arsenicalis was tried, but this, like the salicylates, did not cause any clinical improvement. A lumbar puncture ten days after admission showed a normal fluid, apart from a slight chloride diminution—673 mg. per 100 c.cm.

After seven weeks the patient became very drowsy, and complained a great deal of headache, but there was no vomiting. Neck rigidity and a Kernig's sign developed, but the fundi were still normal and the reflexes unaltered. A second lumbar puncture was done; this showed clear, colourless cerebro-spinal fluid under slightly increased pressure, with a protein of 100 mg. per 100 c.cm., chlorides 637 mg. per 100 c.cm., sugar 48 mg. per 100 c.cm., excessive globulin, and a positive permanganate test, but no cells and no organisms. The blood urea was 44 mg. per 100 c.cm. Epileptiform seizures occurred; a few days later he had four, and died the following day with a temperature of 102° .

POST-MORTEM FINDINGS

Necropsy revealed remarkable pathological changes in various organs. In the heart there was a striking series of nodular thickenings disposed along all the branches of the coronary arterial system, even in direct relation to the smaller intramyocardial branches. Careful examination showed this to be periarteritis nodosa, and examination of the left coronary artery from within its lumen disclosed similar periarterial nodular thickenings and narrowing of the lumen. No intravascular damage or thrombosis was seen. The aorta and pulmonary arteries were normal. The heart muscle showed pallor and evidence of rheumatic carditis, and the mitral valve typical rheumatic verrucose vegetations of very recent origin, this being apparently superimposed upon a more chronic valvular cicatrization. There was no evidence whatever of any malignant endocarditis. The peripheral arteries (radial, tibial, etc.) and cerebral vessels appeared, macroscopically, to be unaffected. The brain was visibly normal. The respiratory tract was clear, and no sinus disease was present. There was diffuse pallor of each kidney, and several small recent infarcted cortical areas. This was associated with diffuse nodular thickenings of the renal arterial system and extreme narrowing of many of the vessels. In the liver, macroscopic nodular arterial thickenings were remarkably widespread. The portal venous system and the biliary tract were normal. Close examination demonstrated that the acute nodular arterial disease had involved the visceral arteries extensively, and this was specially evident in the hepatic, renal, suprarenal, and pancreatic vessels.

The photomicrographic illustrations show the character of the arterial disease. The extensive cellular reaction and narrowing of the vascular lumen is quite remarkable. The presence of inflammatory cells of the type seen in Aschoff tissue reaction is seen, this being especially evident in the section of the vessel in the myocardium.

Comment

The presence of periarteritis nodosa was not clinically suspected in this case, and its detection later was regarded with surprise. The severe precordial pain which could not be explained during the patient's life must have been directly related to coronary arterial disease and consequent myocardial ischaemia. The absence of arrhythmia and bradycardia or any other direct clinical evidence of affection of the conducting mechanism (bundle of His) is

particularly interesting in view of the extensive nature of the coronary and intramyocardial arterial disease.

The epileptiform seizures in the advanced stage of the illness could not be associated with any detectable cerebral, arterial, or other primary intracranial disease. It is surprising, in view of the considerable renal arterial disease, that no further indication than a mild albuminuria was present, and that the blood urea was only 44 mg. per 100 c.cm. The absence of pain in relation to the abdominal viscera is notable; possibly the absence of any arterial haemorrhages or extensive thrombosis explains this latter phenomenon.

Summary

It is evident from a study of the literature and the cases outlined in this paper that the clinical disorder known as rheumatic fever is essentially a disease affecting numerous structures in the body, but with special affinity for damaging the cardiac and arterial structures. The association suggested regarding a common aetiological

agent in these cases is evident, and in the light of recent records it would appear that whereas streptococcal infection or toxæmia in rheumatic fever may confine the tissue damage to certain individual structures—for example, heart valve or nervous system—in other cases a variable degree of severe arterial disease may occur and render itself apparent by any of the symptoms by which periarteritis nodosa is recognized. The possible grave prognostic importance of these latter phenomena is indicated in the cases here discussed.

We are grateful to our senior physician, Dr. Mackey, for his permission to use the case records.

INFLAMMATORY DISLOCATION OF THE ATLAS

BY

DUNCAN C. L. FITZWILLIAMS, M.D., F.R.C.S.

(With Special Plate)

We are all familiar with the curious sequences of cases which sometimes occur in practice, but few people, I imagine, have had two boys walk into their consulting room one after the other with dislocated cervical vertebrae. Yet such happened to me. One was sent by a doctor in Peterborough, and the other by a doctor in Ilford. The cases were as follows.

Case I

A boy, aged 15, whom I saw on February 19th, 1932, was brought to me complaining of stiffness of the neck and pain on certain movements. He was a twin; his sister had died at birth. In July, 1931, he suffered from rheumatic pains in the neck, and in August the neck became stiff, bent to one side, and movements were limited in all directions. Since then movements had gradually improved, but were still limited, especially rotation. During July he had rheumatoid pains in ankles, knees, back, and shoulders, but these gradually decreased and were now rarely felt. About fourteen days previously, when sitting on the ground, his small brother, aged 6, fell against him and bent his neck forwards. The head, however, was in its present position before this accident. An x-ray photograph taken at Peterborough showed displacement of the atlas on the axis. Another taken at St. Mary's Hospital showed anterior dislocation of the left side of the atlas on the axis, with some downward displacement on that side.

EXAMINATION

So identical were the two cases that one description will do for them both. The head was inclined to the left shoulder and the chin directed to the right. The former seemed to be displaced slightly to the left side. It was held stiffly, and voluntary movements were very limited in extent; it could be rotated more to the right than to the left. Flexion was limited after a short excursion, and was painful. The pharynx seemed full, and a prominence could be felt on the posterior pharyngeal wall, especially on the left side slightly above the level of the soft palate, so that it was masked and had to be felt for.

TREATMENT

The condition was explained to the father, who refused to allow any active attempts at reduction. The head was immobilized and an extension apparatus applied with a weight and pulley. The patient was kept lying down in this

apparatus for ten weeks. At the end of this time the pain had disappeared, but the movements of the head, though freer, were still limited. In February, 1933, in a letter stating that the boy had begun to fail about a month after leaving the hospital, Dr. Clapham wrote: "He is gradually losing the use of his arms and legs, and has begun to stagger. He is now very thin, gets up from a chair like a pseudo-hypertrophic muscular paralytic, but can bend to his toes and rise up without climbing up his thighs. His deltoids are wasted, his grip feeble, and his interossei wasted. He has wrist-drop on the right side. My opportunity to overhaul him was limited. There is a swelling below his occiput." Unfortunately Dr. Clapham died, and his successor has not been able to trace the case.

Case II

A boy, aged 10, was brought to see me for stiffness of the neck and pain on moving the head. About four and a half months previously, enlarged glands had appeared in the neck, chiefly on the left side, after a feverish cold, which lasted a week. Hot fomentations were applied for three weeks. Then the patient had quinsy. Five weeks previously he suddenly developed a stiff neck, and held his head stiffly and would not move it. His tonsils were removed in King George's Hospital, as they were thought to be the cause of the trouble. This, however, did no good. The patient constantly supported his head in his hands, except when lying down. Examination proved that the case was exactly similar to the last one.

The x-ray report showed the atlas displaced forward on the axis on the left side—a subluxation. It was thought it might be a developmental error; there was no evidence of caries. His doctor, after I wrote to him, was still doubtful of dislocation, and took him to St. Bartholomew's Hospital, where my diagnosis was confirmed.

I thought that perhaps an injury had been done him while under the anaesthetic for the removal of his tonsils, but the history showed that the wry-neck was established before the operation, which had, in fact, been performed to cure the condition.

SUBSEQUENT PROGRESS

His father refused all treatment, and I did not see him again. I heard a year later that there was considerable improvement in the condition, but the wry-neck still persisted. On January 1st, 1933, Dr. Thomson Brown wrote to say that the patient was in excellent health, but the neck was still obviously dislocated. He had been taken to a bone-setter, who had wrenched his neck about and told him he would be well in six months. He did not improve, however. In January, 1934, Dr. Thomson Brown reported that in the preceding autumn the boy developed tuberculous glands on the left side of the neck. These were curetted in September, and the wry-neck completely disappeared while he was in hospital. The x-ray photograph now shows no signs of displacement.

The dislocation of the atlas vertebrae is very rare, and previously I had never seen a case apart from severe injury. Here, however, were two boys brought by their parents, who had no knowledge of the nature of the trouble.

Cases in the Literature

The condition was familiar from the writings of Grieg and from the excellent paper on the subject by Watson Jones in the *Proceedings of the Royal Society of Medicine*, (February, 1932). He could only find records of eighteen cases. Since that time, however, I have found other cases reported. In most of them the essentials of the history are absent, as the true pathology was not recognized.

Age Incidence and Aetiology

The condition so far, with few exceptions, has been confined to youth, all but two cases occurring under the age of 20. The ages were: at 12 and under, twenty-one cases; at 13 and under, one case; at 15 and under, one case; at 17 and under, one case; at 22 and under, one case; over this age, two cases. In none of the cases was there a history of sufficient violence to cause the condition apart from other factors. Some of them have been dramatic in their suddenness. In one case a nurse was dressing tuberculous sinuses in connexion with the glands of the neck; to see better she gently turned the child's cheek with the back of her hand; the child choked, became cyanosed, and died. Post-mortem examination revealed pressure on the spinal cord by the odontoid process (Reid).

In my first case operation had been performed upon the tonsils, and it was suggested that manipulations of the head, when the child was under the anaesthetic and when the muscles were relaxed, might have accounted for the dislocation. I carefully questioned the father, and he assured me that the stiffness had been noted before the operation, and that in fact it was the stiffness, which was then thought to be due to tonsillar inflammation, that decided him to have the operation performed. In Swanberg's cases the condition was noted after a tonsillar operation, which may have determined it. Fitzsimmons's second case was that of a girl of 8, who, in jumping, fell upon her head, and then had a marked infection of her throat, after which the condition was noted. The patients in Cases 3 and 4 of the same author were also said to have fallen on their heads; in Case 3 there is no mention of any inflammatory trouble, but in Case 4 large glands were noted in front of the sterno-mastoid. In each case the condition was attributed to the accident.

So far there have been thirteen females, sixteen males, and two cases in which the sex is not mentioned.

The Associated Inflammation

This seems to be the dominating factor in all the histories. The inflammation has been in the nasopharynx, upper part of the neck, or near the base of the skull. In youthful patients the inflammation has obviously been of the acute type, situated in the region of the nasopharynx—namely, "sore throat," tonsillitis from various causes, or adenitis of the upper cervical glands; in one case there was periostitis of the mandible (Wittek), and in two cases acute mastoiditis. In older patients both tubercle and syphilis have accounted for the condition. Stammers's case was an excellent example of tuberculous caries in a man of 30.

Pathology

This condition has no well-recognized name. Défossez called it the "maladie de Grisel," while others have invented many methods of describing it. Perhaps in-

flammatory dislocation of the atlas from axis describes it as closely as possible. Concerning the pathology there have been fewer suggestions. Wittek's suggestion that it was due to an inflammation of the tissue round the odontoid process is perhaps the most ingenious. Increased blood supply to a bone has always been associated with a certain amount of absorption of calcium from the bone. This is best seen in the caries which results from tubercle, where the bone is worm-eaten and loses weight to a marked degree; it is a common sight to see candidates in examination weighing a bone in their hands to decide whether it has suffered from tubercle or syphilis. But it was Grieg's observations which brought to our notice that increased blood supply meant decalcification and softening of the bone. With this in mind the true pathological interpretation of the condition became easy.

The accident occurs in young children at a time when the bones have not reached maturity, when they are still growing, are more vascular than adult bones, and, therefore, when they participate more readily in the increased vascularity which accompanies inflammatory processes in their neighbourhood.

We have seen that though this form of dislocation occurs in association with inflammatory processes in the neighbourhood of the base of the skull, a certain period of time is necessary for the decalcification to take place after the inflammatory process has started. This is shown in nearly all cases where a detailed description of the disease is given. These facts are confirmed by x-ray photographs, which reveal that decalcification has taken place in the anterior part of the ring of the atlas. This might be thought to be congenital if it were not for the excellent photographs published by Mr. Watson Jones, which show the ring of the atlas again fully calcified four months later.

The anterior and lateral part of the ring of the atlas is softened by decalcification, and so the attachment of the transverse ligament becomes insecure, and the odontoid process is no longer held in position. All the other ligaments attaching the odontoid to the atlas vertebrae partake in the softening. When this has happened the scene is set for some slight but sudden movement to cause displacement between the two bones, which now have little to hold them together, and the atlas passes forward upon the odontoid vertebra.

It all depends upon the degree of excursion of the bone as to what occurs. If the excursion is bilateral and extreme the odontoid process will immediately press upon the spinal cord and sudden death will result as in Reid's case, quoted above. If the excursion is unilateral and slight only one side will be subluxated, and the spasm of the muscles will fix the subluxation and make up in some degree for the lack of ligamental restraint.

With the passing away of the inflammatory process recalcification will take place, and it may be that the subluxation will be reduced of itself, but the edges of the articular processes are sharp and well defined, and tend to hitch the one on to the other; this makes spontaneous reduction difficult. Nevertheless, it has occurred quite unexpectedly in several cases, early in one of Fitzsimmons's cases, and after two years in one of mine, where it may have been helped by manipulation of the neck during the curetting of the tuberculous glands.

Clinical History

The histories are mostly similar, and seem to register a very clear picture of the condition. The child has an inflammatory condition of the nasopharynx or upper part of the neck. One to two weeks later stiffness of the neck is complained of, and the head is held in a wry-neck position. In most cases there is no history of violence,

and the matter is treated as part of the inflammatory process, which indeed it is. In one or two cases where there has been a fall it is not quite clear if the condition was due to it, though in some cases violence was adjudged the cause.

The child assumes the ordinary position of wry-neck, and there is a certain amount of rigidity and fixity of all the muscles of the neck; and movements or attempts at movements are resented as painful. At first little is thought of the condition; in few cases is it considered necessary to have an x-ray photograph taken at this time. In those cases, however, where a photograph has been taken several things are noted. There is a distinct subluxation of the atlas upon the odontoid and a marked lessening of the shadow of the anterior part of the atlantoid ring compared with the bones lower down the neck; indeed, this may be so marked that a congenital defect may at first be suspected.

In the commoner unilateral subluxation there is no pressure on the spinal cord, owing to the ample space provided in this region, though this must be encroached upon. Pressure symptoms have been noted to come on almost at once, as in Ogilvy's case, where they appeared on the fourth day and disappeared again on the eleventh; or they may come on late, as in my first case. On examining the pharynx with the finger a distinct irregularity and protrusion of bone can be felt at the level of the soft palate. This is more evident on one than the other.

Treatment

A correct recognition of the factors of the condition will dictate the line of treatment to be advised. Whether control of the neighbouring inflammatory process is the first essential step, or the old rule of reducing a dislocation at the earliest possible moment is the most important, is difficult to decide. In most cases, however, considerable time has elapsed before the diagnosis is made and the case comes to the surgeon, so that the question does not arise, and then replacement at any early date is to be desired. This method was adopted in Mr. Watson Jones's two cases with complete success. The head was fixed in plaster for ten weeks; this was followed by exercises and a return to normal. No surgeon with any imagination, however, will contemplate this form of treatment lightly. The anaesthetic, by relaxing the muscles, removes the last barrier to the free movements between the two bones, and with free movements sudden death is likely to ensue. After reduction the application of a bandage round the neck cannot be altogether free from danger. In most cases it would be necessary, frankly, to explain the risks to the parents. In my two cases the parents at once vetoed any active treatment; although in one the parent had no objection later to a bone-setter wrenching the boy's neck.

One is therefore reduced to fixing the head in the wry-neck position with weight and pulleys to see if reduction will occur as the deformity and disability become less. I have no doubt also that at the tender age of most of these patients the gradual development of the parts will render less and less apparent any deformity which might ensue. Some of the patients have been kept in the recumbent position for months with excellent results.

My own belief is that these cases are more common in a slight degree than is generally supposed, and that many of the temporary wry-necks associated with inflammation of the upper part of the neck are in reality such cases in a mild form, which rectify themselves and leave no trace. It is certainly curious that if one case has been recognized and impressed upon the memory, other obvious ones seem to be encountered shortly afterwards.

GUMMA OF THE BRAIN

WITH A REPORT OF A CASE TREATED SURGICALLY

BY

J. E. PATERSON, M.B., Ch.B., F.R.F.P.S.G.

NEUROLOGICAL SURGEON, VICTORIA INFIRMARY, GLASGOW;
 CONSULTING NEUROLOGICAL SURGEON, GLASGOW EYE
 INFIRMARY

AND

MARGARET LESLIE, L.R.C.P.

MURHEAD SCHOLAR, CLINICAL LABORATORY, VICTORIA INFIRMARY,
 GLASGOW

(With Special Plate)

There is a very prevalent belief that gumma of the brain is rather a common form of intracranial new growth, but this view is not borne out by statistics. Thus Cushing,¹ whose figures cover a period of thirty years and go back well into the pre-Wassermann and pre-salvarsan era, had only twelve cases of gumma among his two thousand patients with verified intracranial neoplasms; Sachs,² again, had but four cases in eight hundred intracranial operations—that is, 0.5 per cent. of the whole. Gumma cerebri is thus to be regarded as decidedly among the rarer types of space-occupying lesions of the intracranial cavity, and it is felt that operations for the condition are of sufficient rarity to justify the publication of the case reported below, while the unusual features of the lesion, and the resultant difficulty in the differential diagnosis, make it one of special interest.

Case Record

A. A.; 37 years, a hammerman, was transferred to the Victoria Infirmary from Kilmarnock Infirmary on February 21st, 1934, suffering from headaches, mental deterioration, Jacksonian epilepsy, and gradually increasing right-sided paresis, of eight months' duration.

There was a definite history of syphilitic infection, diagnosis of which was made in 1919; energetic treatment followed, after which his Wassermann reaction, previously positive, had become negative.

In July, 1933, he came home from work complaining of very severe pains in the head. These persisted, and two weeks later he had his first Jacksonian seizure. Further fits followed at varying intervals; occasionally he would have two or three in twenty-four hours, at other times periods of freedom of several days would occur. Gradually it was noticed that he was losing power in his right hand, and later the right leg became involved also. This was his state when he was admitted to Kilmarnock Infirmary on October 13th, under the care of Dr. Hamilton and Dr. Currie, and thereafter, in spite of energetic anti-syphilitic treatment, his condition gradually deteriorated, and by the end of October he was bed-ridden. The fits continued, as did the severe headaches, and latterly these had been associated with periods

of drowsiness, while his mental state had deteriorated very noticeably.

The fits were typically Jacksonian; starting in the right thumb and forefinger, the clonic spasms spread gradually up the limb to elbow and shoulder, finally involving the right side of the face. Except on one doubtful occasion, consciousness was never lost, while the fits were invariably followed by a temporary aggravation of the paresis.

Examination.—On admission to the Victoria Infirmary he presented the following appearances: a tall, thin, pale, and obviously ill man, he was noticeably drowsy and incooperative, and answered questions with difficulty and with marked inaccuracy; so much so that his story, when checked with that from other sources, was found to be false in almost every detail. X-ray examination of the skull was negative; the Wassermann reaction of the blood was positive. The following signs were found on neurological examination. The fundi were normal, as was the visual acuity, while the visual fields, as far as could be ascertained, were full. There was a right-sided facial paresis of the upper neurone type, moderate in degree; the tongue deviated to the right when protruded. It was impossible, because of his mental state, to test his sensory functions, while the extreme hemiparesis made an examination of gait and station impossible; the right arm and leg showed a very marked palsy of upper motor neurone type, more pronounced in the upper limb, with marked spasticity and some contracture of fingers, wrist, and elbow. The right arm reflexes were exaggerated, as was the right knee-jerk, while the right plantar reflex was extensor, with ankle-clonus.

Operation.—This was done on March 7th, 1934. Under local infiltration with novocain, supplemented with morphine and scopolamine, a large bone-flap was turned down over the lateral aspect of the left hemisphere. The bone was rather thicker and more vascular than normally. The dura, whose surface appeared normal, was under moderately increased tension. When a dural flap had been turned down the exposed convolutions were found to be everywhere yellow, oedematous, and flattened, especially in the upper part of the field.

In this region, in the upper portion of the post-central gyrus, was a rather depressed, sharply defined area, about a centimetre in diameter, the surface of which presented a firm, purplish-grey appearance. In order to obtain a piece of tissue for examination an incision was made in this area, when at once a quantity of thick material like pus poured out. The possibility that we were dealing with a chronic brain abscess occurred at once, and the incision was hastily plugged with a pledget of cotton, while a report on the characters of the purulent fluid was awaited. It proved to be composed largely of mononuclears, while no organisms could be seen in smears, and on the strength of these findings a diagnosis of a breaking-down gumma was made, and it was decided to try extirpation of the lesion.

Complete evacuation with the sucker was followed by occlusion with silver clips of a few small cortical vessels running into it, and thereafter it was possible to seize the thick fibrous wall and gradually remove it from its bed by traction, combined with gentle wiping away of the adherent brain with cotton pledgets wet with Ringer's solution. Ultimately the capsule was removed intact, but in a rather torn state, so that measurements were difficult, but it was estimated that the lesion, before evacuation of its contents, was probably about the size of a small hen's egg. The dura was closed completely, the cavity left by the removal of the gumma being drained by a small strip of rubber dam. The bone-flap was replaced and the scalp sutured in the usual way.

Pathological Report.—The tissue, which was examined microscopically, was definitely gummatous, and no difficulty was experienced in recognizing it. In sections taken from different portions of tissue the different areas which compose a gumma could be identified. In the periphery there was an area of dense character, encapsulating the more cellular and the softened tissue, and forming a wall of demarcation from the surrounding congested brain tissue. This area showed connective tissue cells of new-formed character, mixed with cells of lymphocytic and polymorphonuclear type. An area which was more cellular and highly vascular was situated internal to this. The features of this part of the section were the numerous dilated and well-filled blood vessels, and groups of

cells of epithelioid and plasma type. The central area was necrotic, and showed softening and caseous change. In this area cells of inflammatory character, polymorphonuclear and mononuclear in type, were present with occasional giant cells of irregular outline, and with no attempt at tubercle formation. Both in the new formation and in the adjacent brain tissues groups of mononuclear cells almost resembling septic foci were seen; but the softened contents from the cyst-like cavity showed no evidence of pathogenic or tuberculous organisms.

The vascular changes were quite definitely those of a syphilitic lesion. A large number of the blood vessels showed thickening of their intima with swelling of the endothelial cells, and a few revealed an obliterative endarteritis. Other vessels showed a periarthritis with a distinct appearance of cuffing of the vessel wall.

Progress.—Recovery was uneventful, and the patient was discharged to a convalescent home on March 22nd, when he could already walk across the ward with some assistance. A mild degree of aphasia, present since the operation, was showing some signs of improvement. He reported again on May 3rd, when his condition had greatly improved. He walked with a barely noticeable limp, his former aphasia being shown only by some hesitancy in speaking and an occasional difficulty in finding a word. There was still some spasticity and weakness in the right hand and arm. Mentally he was a transformed individual, alert in manner, and displaying a pronounced sense of humour when he related his recollections of his pre-operative state.

Discussion

Forty years ago the treatment of brain tumours, despite a few brilliant successes by Horsley and Macewen, was in an early stage of evolution, while the discovery of the Wassermann reaction was still ten years distant. The customary treatment of a case of suspected cerebral tumour was a lengthy course of mercury and potassium iodide, on the principle that if antispecific treatment failed but little remained to be done. In 1893 Sir Victor Horsley³ read his classical paper in which he pleaded with the profession to shorten this period of antispecific treatment to six weeks, and urged that they should hand over to the surgeon any brain tumour patient whose condition had not very definitely improved by then.

In 1934, however, thanks to the great advances in the technique of intracranial surgery and to the development of the Wassermann reaction, Horsley's plea has become of historic interest only, and in the vast majority of cerebral tumour cases the finding of a negative Wassermann reaction is now followed by speedy recourse to operation. Cases of true brain tumour do, however, occur in which the blood or cerebro-spinal fluid shows a positive reaction, a fact perhaps sometimes not sufficiently appreciated by the physician. Moersch⁵ has said: "None of the serological data, the condition of the fundus, nor any one cardinal symptom are pathognomonic of either brain tumour or syphilis"; while Martin⁶ describes two cases of brain tumour with positive Wassermann reaction which were treated for lengthy periods by antispecific measures, and points out that the presence of a positive reaction does not necessarily mean that the symptoms of involvement of the nervous system are of syphilitic origin. Bagdasar,⁷ again, in a paper from Cushing's clinic, states that the neurologist is still too much inclined to see specific lesions whenever the Wassermann reaction is positive in the blood or cerebro-spinal fluid, and maintains that what he terms this "abuse of the diagnosis of nervous syphilis" is very widespread to-day among neurologists.

Even granted that a lesion is of syphilitic origin, it should, however, be emphasized that antispecific treatment may be quite ineffective. This can be readily seen to apply in such a case as ours, in which a thick, fibrous wall isolated the interior of the lesion from its surround-

ings. Horsley pointed this out many years ago, and demanded concrete proof of the healing of a cerebral gumma by medicinal treatment. In this view he was supported by Puusepp,⁶ who holds also that certain cases of chronic syphilitic meningitis should be submitted to surgical treatment when uninfluenced by iodides, and claims good results. Martin,¹ again, points out that there are cases of syphilis of the nervous system in which operation may favour the activity of medical treatment, when this was previously of no avail.

Altogether, there is much to be said for Bagdasar's view when he writes:⁶ "Ainsi donc, nous conseillons d'opérer toujours les malades suspect d'être atteints de gommages cérébrales, l'opération montrera d'ailleurs le plus souvent qu'il s'agit d'une tumeur cérébrale et très rarement d'une gomme."

We may sum up the position by saying that our attitude towards gumma of the brain should be that of Horsley towards cerebral tumour forty years ago—if no improvement results after a short course of medical treatment the case should be handed over to the surgeon for removal of the lesion, or, failing this, for decompression.

A very unusual feature in our case is the extraordinary resemblance the lesion presented to a chronic encapsulated intracerebral abscess. In the literature available we have failed to discover any note of a syphilitic focus with such appearances in this situation, although one is familiar with the occurrence of pronounced central liquefaction in gummata in other organs, notably in the liver. Again, Garland and Armitage⁷ have stated in a recent paper that gumma of the brain is to be distinguished from tuberculoma in that it is probably always attached to the dura mater, and in this our case provides the exception to the rule, the dura being neither adherent nor otherwise involved. The point to be noted is, however, that in the differential diagnosis of gumma the fact of its rare simulation of chronic brain abscess should be borne in mind.

We must express our indebtedness to Dr. Currie, Dr. Hamilton, and their house-physician, Dr. Gemmill, for very careful notes of the patient's condition during his stay in Kilmarnock Infirmary, while to Dr. John Anderson, director of the clinical laboratory, we wish to tender our thanks for his examination and confirmation of our slides, and for a great deal of valued help.

The following international medical post-graduate courses will be held in Berlin this autumn. From October 1st to 13th there will be a course in internal medicine with special regard to tuberculosis, followed by a course in tuberculosis from October 15th to 20th. Throughout this last-named week there will also be a course in obstetrics and gynaecology. A post-graduate course in diseases of the ear, nose, and throat will extend from October 1st to 13th; another in paediatrics from the 22nd to 27th; and a third in surgical intrathoracic disease, with special reference to pulmonary tuberculosis, from October 29th to November 2nd. Individual training classes in all branches of medicine are held each month, including bedside and laboratory practice, and concentrating on practical work rather than on theoretical studies. Programmes and further particulars are obtainable from the Berlin Academy for Medical Post-Graduate Training, Robert Koch Platz 7, Berlin, N.W.7.

CAESAREAN SECTION

DELIVERY OF 254-DAY EXTRAUTERINE FOETUS

BY

ARCHER HOSKING, M.D., CH.M.ED.

MASTERTON, NEW ZEALAND

(With Special Plate)

Modern textbooks give good descriptions of the methods of escape and survival of the ectopic foetus. I find them especially lucid in *Diseases of Women*, by "Ten Teachers." Whitridge Williams includes a long bibliography, while Gould and Pyle (*Anomalies and Curiosities of Medicine*, 1898) give a summary of recorded cases to that date.

It would appear that operation has generally been very much more difficult than in the case recorded below. This happy state of affairs followed on the complete retention of the placenta within the tube, no part escaping to form general adhesions. A factor in the non-recognition of the condition was the position of the sac above the

FIG. 1.

- A, Omental sac containing foetus.
- B, Foetal head.
- C, Omentum in front of placenta.
- D, Position of omental adhesions to abdominal wall.
- E, Uterus below placenta.
- F F, Colonic flexures.

uterus, and its growth upwards as if in continuity. It is consoling, however, to find it stated, on the authority of the "Ten Teachers," that these cases of erosion "may show no symptoms to suggest that pregnancy is in any way abnormal."

I am not able to state just when complete erosion of the gestation sac took place. Probably the extrusion of the foetus in its unruptured amnion was slowly progressive. The fixation of the lower omentum to the old scar evidently held it in such position that upward growth pushed the foetus between this and the transverse colon, enabling a wrapping of omentum to form a protecting nest. I think Fig. 3 explains this. Of the other illustrations in the text, Fig. 1 shows the position as first observed on opening the abdominal cavity. Fig. 2 shows the position of the parts with omentum removed. The foetus is above the enclosed placenta, while the cord and tubal isthmus diverge from the tubal rent. It also shows the amniotic cap on the foetal head, and the position of the adherent transverse colon.

Case Record

The patient was a woman, aged 35, who had been married for eight years, and who gave the following history. Beyond slight indigestion and constipation she had always been healthy, the menstruation being regular and free from pain. Five years ago, three years after her marriage, I had operated on her for right-sided ectopic gestation at about the seventh week. The left tube and ovaries were normal, and recovery was uneventful. There had been no other pregnancy. Menstruation had continued normally.

PRESENT ILLNESS

First consultation, August 15th, 1932. The patient complained of weight in the pelvis and constipation, and was ten days over her menstrual time, the last period dating July 5th, 1932. Menstruation did not recur, and vaginal examination during the second and fourth months showed apparent enlargement of the uterus in keeping with corresponding stage

of pregnancy. The position was good, and the parts were freely movable. There was nothing abnormal to note in connexion with the adnexa. The urine was normal. Constipation continued, accompanied by pain across the abdomen below the umbilicus. Evacuation of the bowel was difficult, but relief was afforded for twenty-four hours or more by the use of enemata. This condition persisted all through the pregnancy, becoming steadily worse, and constituting a source of much anxiety: it was attributed to adhesions from the previous operation. Apart from the constipation and associated pain there was no other abnormal symptom.

The uterus was not examined per vaginam between the sixteenth and twenty-sixth weeks, but frequent observation was made by palpation through the abdominal wall. The increase in size was still in keeping with the duration of the pregnancy. During the seventh month it was noted that the foetus lay persistently transverse, with the head to the left,

the body of the child being high. Examination revealed no parts of a second foetus, but a resistant mass above the pelvic brim and below the foetus raised the question of cystic tumour or foetal abnormality. This mass increased noticeably during the eighth month, at which time the foetus was also developing well.

On the 250th day of pregnancy I took an x-ray picture of the abdomen (see Special Plate). After consultation, arrangements were made for Caesarean section, but as the patient was fairly comfortable, and as it was desired to give the child all the time possible, operation was delayed until the 254th day. The foetal heart had ranged at 140, but during the last day before operation it rose to 174. During this last, twenty-four hours the mother had intermittent severe pains, as if in labour.

OPERATION

On March 16th, 1933, using avertin and subsequent ether, I made a lower mid-line incision, and found easy access. The condition can best be understood from the accompanying drawings, which are from rough sketches made at the time. The foetus lay outside the uterus in transverse position, head to the left. It was close up under the liver and stomach. Below was a rounded tumour comparable in size to a six

months pregnant uterus. The omentum was adherent along the old abdominal scar, and covered the greater part of the lower mass. The foetus was covered behind, above, and in front by a thickened and fibrosed omental sac. The transverse colon lay at the back, below the foetus, being firmly adherent to the tumour, which formed the lower part of the sac in which the foetus lay. Apart from these adhesions the colon was free at each side, and the small intestines were wholly free.

The child was delivered through the anterior layer of the omentum. The sac contained an amount of meconium-stained fluid estimated at about 16 ounces. There were ill-defined foetal membranes lining the sac. The top of the child's head was enveloped in a close-fitting cap stronger than the rest. Exploration of the tumour mass below was easy, as there was not much in the way of adhesions. It consisted of a normal-sized placenta within the distended tubal ampulla, which was tough and firm. It lay free, except for adhesions to the transverse colon and light omental adhesions at its upper pole. It was not adherent to the anterior apron of omentum behind the old scar. At its base there was an opening, through which the cord emerged to ascend to its foetal connexion, and through which the foetus had escaped from the tube. The cord was well developed, and of medium length and thickness. Below the opening the tubal isthmus, much thickened (1 in.) and elongated (6 in.), led to the left uterine cornu.

The uterus had reached the size of a two months pregnancy. It was fitted into the base of the tubal mass in such a manner as to give, on first examination, the impression of a continuous whole. The stump of the right tube, remaining after the former ectopic operation, and a small right ovary, were attached and free from adhesions. The overgrown tube containing the placenta was detached at the uterine cornu. The only difficulty in completing its removal was the separation of the transverse colon. Omental tissue covered these defects. A large rubber tube was inserted to carry off oozing products, the upper omental cavity being left to drain into the lower area. There was no trouble with bleeding.

CONDITION OF THE INFANT

The child, a female weighing 5 lb. 12 oz., was born alive, and there was little difficulty in establishing breathing. It was a normal pink baby, with hair and nails in keeping with its development. It only survived nine hours; for most of that time it breathed well and was of good colour, but did not cry. In spite of the attention of a capable nurse life could not be maintained.

CONDITION OF THE MOTHER

The patient suffered much nervous reaction following the operation. On the second day she had five epileptiform convulsions. These came on suddenly, as if she had had a smack in the face, and were followed by spasm and convulsion of the whole body. Within fifteen minutes they passed off, and she was quiet and conversing again. They did not recur. She complained of dullness of vision with flashes before her eyes, and at times was forgetful and irrational. The urine was normal, the bowels acted well, there was no distension, and she took nourishment well. Her blood pressure was 144 systolic, reduced to 115 at the end of a fortnight. The temperature did not go above 100° F., though the pulse was 110 to 120 during the first week. There was not much discharge from the wound; the drainage tube was removed on the third day, the stitches on the tenth day, and the wound healed without trouble. There was slight bleeding per vaginam on the third, fourth, and fifth days, followed by a uterine cast on the sixth day. This was complete, and measured about 3 by 2½ inches when spread flat.

Unfortunately, convalescence was interrupted at the end of the third week by a venous thrombosis of the left leg. The patient was, however, discharged at the end of seven weeks from the date of operation. She is now (after twelve months) in good health, and can drive a motor car and engage in the usual activities of life. Her menstrual periods returned at the end of the third month after operation, and have remained normal. There is very little trouble from constipation.

A CUTANEOUS MANIFESTATION OF VITAMIN A DEFICIENCY

BY

G. P. GOODWIN, B.A., M.R.C.S., L.R.C.P.
HOUSE-PHYSICIAN, QUEEN'S HOSPITAL FOR CHILDREN, LONDON
(With Special Plate)

The published records show that vitamin A deficiency is common in other parts of the world at the present time, but until about a year ago the occurrence of this condition in man had only been diagnosed with certainty when eye changes such as night-blindness, xerophthalmia, and keratomalacia had been found.

The case reported below suggests that minor forms of vitamin A deficiency in this country are commoner than supposed, and may at the same time show signs distinct from those already mentioned.

SYMPTOMATOLOGY OF SKIN LESIONS

Writing of cases of vitamin A deficiency seen in China, Pillat¹ describes certain skin lesions. He says that in severe cases of vitamin A deficiency the skin feels dry and becomes scaly; a marked reduction of sweating is noticeable and comedones may form. The nails become dry and brittle. Nicholls,² working in Ceylon amongst prisoners living on a diet inadequate in vitamin A and other constituents, also describes the dry skin. Minute, hard, dark-coloured papules appeared in these cases, their distribution being on the legs, abdomen, shoulders, and elbows. On examination, the papules were found to consist of enlarged sebaceous glands plugged with altered sebum. They did not tend to suppurate, but hard, dry, thin scabs formed over and around the papule. A similar papular eruption is described by Loewenthal.³ It was first observed by him during a quarterly inspection of the Uganda central prisons. The prisoners had been fed on diets low in vitamin A content, and it was found that every sufferer with other signs of vitamin A deficiency—namely, xerophthalmia and night-blindness—showed cutaneous changes in addition. Clinically, the skin was dry, this dryness affecting the whole body with the exception of the face and scalp. A papular itching eruption was present with a limited distribution. It was found chiefly on the extensor aspects of the arms, and on the front and outer surfaces of the thighs. From eighteen patients papules were excised and examined microscopically. The papule arose from a pilosebaceous follicle; the mouth of the follicle was sealed with a plug of horny tissue, among which polymorphonuclear leucocytes and lymphocytes were demonstrated. Eighty-one prisoners were segregated for observation, and of these seventy-one suffered from night-blindness, forty-five with xerophthalmia, and seventy-four with the skin lesion. For these cases no local treatment was given for the skin. The diets remained unchanged except that 1 oz. of cod-liver oil was given daily to each man. After nine weeks' treatment all cases with night-blindness and xerophthalmia were cured, while 98 per cent. of the dermatoses were also cured. From Nyassaland, twenty-three years ago, there came a report of similar skin lesions. Stannus,⁴ working amongst cases of pellagra, found that a few patients manifested a skin condition quite distinct from that associated with pellagra. It consisted of a folliculitis with retention of secretion; the enlarged follicles were prickly to the touch, and had a black areola.

Dr. Stannus and Dr. Loewenthal have kindly seen the case described below and have stated that the skin presents the same features as shown in their own cases.

CASE RECORD

History.—T. H., a male aged 10 years, was admitted to the Queen's Hospital for Children on April 16th, 1934. One week previously he had attended the casualty department for sore throat, vomiting, and abdominal pain, for which he had been ordered a milk diet. On the 15th his mother noticed a rash on his body, though it is certain from the

The ninth conference of the International Union against Tuberculosis will meet in Warsaw on September 4th, 5th, and 6th under the patronage of His Excellency the President of the Republic of Poland and under the chairmanship of Professor Pietrzynski. The discussion will be limited to three main subjects. Biological subject: "Biological Variations of the Tubercle Virus," opening report by Professor Karwacki (Poland). Clinical subject: "Tuberculosis of the Bones and Joints: Treatment, medical and surgical," opening report by Professor Putti (Italy). Social subject: "The Use and Organization of Tuberculosis Dispensaries," opening report by Professor Léon Bernard (France). The organization committee has prepared an attractive programme of receptions and excursions; the latter will enable members of the congress to visit the chief anti-tuberculosis institutions as well as the most picturesque scenery in various parts of Poland. Members of the International Union are invited to take part in the conference without fee. Persons who are not members of the Union and who wish to take part as members of the conference must forward their application, together with a contribution fee of 50 zlotys, exclusively through the medium of the National Association for the Prevention of Tuberculosis, Tavistock House North, Tavistock Square, London, W.C.1. Reductions on hotel prices and railway fares will be granted to members of the congress.

character of the eruption that it had been present for much longer. In answer to a direct question, the mother said that she thought the skin had been dry for several years. The general health of the boy had been good, although he had never been a vigorous type of child. On questioning it was learnt that his diet previous to April 8th had consisted of the following:

Breakfast.—Bread, jam, tea, with skimmed condensed milk; occasionally butter.

Dinner.—Generally fish with potato. The fish consisted of either dried boiled haddock, or of dogfish, the latter bought fried at a fish shop. Sometimes a sausage or the yolk of an egg was given, the yolks totalling three per week or less.

Tea.—Bread and jam; tea.

Supper.—Bread and jam.

His mother stated that the child disliked meat and green vegetables, cow's milk, milk puddings, and white of egg, and that he had not touched meat for years. According to the mother there had been no important previous illnesses and no previous skin eruptions, but the accuracy of these statements cannot be relied upon. There was one other child in the family, who was having a better diet, and who, on examination, manifested no abnormalities. The diet of the patient presents a low content of vitamin A—the breakfast, tea, and supper provided practically none of it, while on certain days of the week the vitamin content of the dinner was also low in vitamin A value.

State on Admission.—The boy was pale, and appeared to be too ill to stand up for any length of time. He was not thin, and was fairly well grown. His height was 4 ft. 6 in., and weight 4 st. 3 lb. He was apathetic, and wanted to lie down, but answered questions intelligently. The temperature was 100.4° F. His skin was dry, except on the face, the dryness being particularly noticeable over the legs and feet. An eruption was present, and consisted of hard, dry papules, one to two millimetres in diameter, many of them red in colour. Thin scales were present over and around each papule, while in the centre of the papule was a pin-point of dry material, looking silvery under a lens, plugging the sebaceous gland around which the papule had formed. The papules were reddish in colour, largest, and most numerous on the extensor surfaces of the lower limbs. Other areas affected were the extensor aspect of the elbows, both shoulder regions, the buttocks and sacral region, and a small patch in the right pre-auricular region. There were numerous horny-looking comedones on each knee; the nails of hands and feet looked drier than normal; the hair and scalp appeared normal. A small area of moist eczema was present at the left angle of the mouth.

The eyes showed no xerosis, but there was injection of the vessels of the conjunctiva running from the inner and outer canthi of the eye to the cornea. A distinct yellowing of the scleral conjunctiva was also present. Examination for evidence of night-blindness proved negative. There was no hoarseness; the tongue was red and smooth, being denuded of its superficial papillae, while the gums of the upper jaw were swollen, retracted over the carious upper incisors, and presented the appearance of pyorrhoea. The heart, lungs, and alimentary and central nervous systems showed no abnormalities. The stools were normal and there was no abdominal pain or distension. There was no excess of epithelial cells in the urine. A blood count showed little abnormality. Red blood cells, 4,020,000 per c.mm., haemoglobin, 88 per cent.; colour index, 1.0; white blood cells, 13,700 per c.mm. (polymorphonuclears 80 per cent., lymphocytes 14 per cent., hyalines 4 per cent., basophils 2 per cent.).

Treatment and Course of Illness.—No local treatment was applied to the skin, and the diet given included meat, eggs, fish, green vegetables, milk, and butter. For the first few days in hospital the boy refused meat, but has since taken it readily. Four drachms of cod-liver oil were given daily by mouth, and at the end of a week there was a marked improvement in his general condition. There was slight pyrexia at first, but in four days the temperature reached 98.5° F., and at the end of his first week in hospital the child appeared more vigorous and started voluntarily to sit up in bed. The skin became less dry and scaly, and at the end of a fortnight the papular rash commenced to subside. In about six weeks the skin looked and felt almost normal, although tiny horny plugs could still be seen and felt, plugging the sebaceous glands of the skin; this was particularly noticeable over

the legs. When these plugs were extruded a small crater-like orifice, as described by Loewenthal, could sometimes be seen with a lens. Eye pigmentation disappeared, and the injected conjunctival vessels subsided. The gums looked healthier at the end of the third week; the tongue papillae had also regenerated by this time.

At the present time children attending the medical outpatient department at the Queen's Hospital for Children are examined for evidence of similar cutaneous lesions. Already several cases have been found with apparently similar lesions of much slighter grade, and in each of these cases there is a history of a diet which by ordinary clinical standards is inadequate. Each child has been given a preparation of vitamin A, and the results which have so far been obtained are encouraging.

SUMMARY AND CONCLUSION

A case is described in which the diagnosis of vitamin A deficiency is based: (1) on the presence of a dry, harsh "goose-skin," with a papular eruption most marked on the extensor surfaces; this eruption being similar to that described by Loewenthal and his associates and by Nicholls and others; (2) on the history of a diet almost certainly deficient in vitamin A; (3) on the complete disappearance of the cutaneous abnormalities when the boy was given a good mixed diet with the addition of cod-liver oil.

I would like to thank Dr. Helen Mackay for her kindness in allowing me to publish this case, and for her helpful criticisms.

Note by Helen M. M. Mackay, M.D., F.R.C.P.

In a recent article in the *Archives of Disease in Childhood* I have suggested that the eye symptoms of vitamin A deficiency are not necessarily the earliest symptoms of this condition. Since writing that article I have had the privilege of discussing the question with Dr. L. J. A. Loewenthal and Dr. W. H. Kauntze, both of the Uganda Medical Service, and have read the valuable article by Dr. L. Nicholls, who is working in Ceylon. From their observations it is, I think, established that it is often possible to diagnose vitamin A deficiency from the cutaneous changes alone. That the skin changes which they describe are due to vitamin A deficiency seems certain. Keratinization of epithelial tissues is generally regarded as the characteristic pathological change resulting from vitamin A deficiency, so that the skin lesions they describe fit perfectly into the picture. Moreover, the administration of cod-liver oil alone, or, in two cases, of a concentrate of vitamin A alone, regularly brought about cure of the skin changes in Dr. Loewenthal's cases. The case here described by Dr. Goodwin is without doubt of the same type. Since seeing this child we have been on the look out for other such cases in the outpatient department of the Queen's Hospital for Children, and have already found several children with a slight grade of an apparently similar condition of the skin. In each of these patients there is a history of a poor and ill-balanced diet. If by the therapeutic test of giving vitamin A a number of such cases can be shown to be due to a deficiency of this vitamin, it will be established that this deficiency is far from rare in this country.

The vacancy caused by the death of Dr. H. Watson Smith, medical director of the Lebanon Hospital for Mental Diseases, at Beirut, in Syria, has now been filled. The London General Committee of the hospital has secured the services of Dr. R. Stewart Miller, late medical director of the Khanka Mental Hospital, near Cairo, who retired from that post a year ago under the agreement whereby Egyptians replaced British civil servants. Dr. Miller brings to his new work great experience of mental diseases and administration, as well as the knowledge of Arabic and French which is so necessary in Syria.

Clinical Memoranda

LATE RECURRENCE OF CARCINOMA

(With Special Plate)

The following case is, I believe, worth recording.

A woman aged 61, a matron's assistant, came to me on March 24th, 1933, complaining of shortness of breath, loss of weight, and insomnia; the latter she attributed to having retired from her employment. I saw her again on July 17th, when she complained of lumps on her head and pains in the arms and back. She had lost 2 st. in weight, and was very sallow. There was a swelling the size of half a walnut on the left eyebrow, soft in the middle, and fading into the frontal bone; several small lumps were scattered over the scalp, much concealed by hair. She then stated that she had had an operation on the vulva in 1921, and this was confirmed by Dr. E. F. Page of Solihull, who wrote saying she had had the vulva excised for epithelioma.

X-ray photographs, taken on July 24th, showed many areas of rarefaction, of all shapes and sizes. The Wassermann reaction on July 21st was negative. The right ilium was swollen to the size of a large orange, with areas of egg-shell crackling, but there was no sign of recurrence in the vulva. The cancer cells appear to have remained dormant for twelve years in the ilium before becoming disseminated. I had permission to take a section from the scalp and ilium, and Dr. S. C. Dyke kindly reported on them.

Report on Nodule from Scalp

Such parts of the edge of the tumour mass as are available for examination show a well-formed fibrous tissue capsule limiting the periphery of the tumour. The tumour itself consists of spheroidal and polygonal cells; it is almost without stroma, the cells lying irregularly packed against each other. In one or two places a fibrous tissue stroma is present, and here the tumour cells appear to be growing from the fibrous tissue core after the manner seen in papillomata. The cells are large, with somewhat reticular nuclei and bulky cytoplasm staining densely with eosine. They are highly anaplastic and dedifferentiated, and it is impossible to state their type with certainty. They suggest an origin in squamous epithelium, but none of them show prickle cells, and there is no evidence of either eleidin or keratin formation. Free haemorrhage has occurred in certain parts of the tumour mass.

I am much indebted to Mr. Patrick for his help in this case, and to Dr. Dyas and the Royal Hospital for the x-ray photographs and report.

Wolverhampton. C. L. SPACKMAN, M.B., Ch.B., D.P.H.

A CASE OF ABDOMINAL PREGNANCY

The following case seems sufficiently unusual to merit record.

E. B., a married woman 32 years of age, was admitted to the Glendon Hospital on February 14th suffering from pain in the lower abdomen. She gave a history of amenorrhoea extending over a period of seven and a half months. She had had three children, the last being about 5 years old. On palpation of the abdomen the fundus uteri was found to be just below the level of the umbilicus; the external os was not dilated, and there was no sign of bleeding. Sedatives were prescribed for pain, and she was kept in bed. Her symptoms subsided within a week, but she was not allowed up until the twelfth day. Two days later she was discharged from hospital feeling much improved. On March 13th she was readmitted to hospital, again suffering from severe abdominal pain. The fundus uteri was just above the level of the umbilicus, and as no foetal or maternal sounds were audible on auscultation of the abdomen, a diagnosis of dead foetus was made. On March 23rd an attempt was made to induce labour by the insertion of bougies into the uterus, and it was then found that the bougies could not be inserted beyond half their length. On the following day the patient had slight labour pains, and the bougies were expelled along with a small amount of blood. Following this the pains subsided and all bleeding stopped. On the morning of April 6th the patient was again seized with severe pain in the abdomen, which was now markedly distended and rigid.

She had a temperature of 102° F., and a pulse of 110. Laparotomy was advised, but the patient refused to agree to any surgical intervention. Next day her condition was worse and she at last gave consent to operation.

The abdomen was opened by a right paramedian incision, and the parietal peritoneum was found to be much thickened—in some places a quarter of an inch thick. The peritoneal cavity was filled with blood, and a dead female foetus of about eight months' development was found lying in a "false uterus" made up of parietal peritoneum, transverse colon, and great omentum, coils of small intestine, and the pelvic peritoneal pouches. The placenta was implanted upon the great omentum and transverse colon, and coils of small intestine. By ligating the omentum in several places the placenta was cut away from it, but it was quite impossible to remove all placental tissue from the coils of small intestine for fear of causing grave injury to the bowel. After removing all that could be removed of placenta, the uterus and tubes came into view, the former being somewhat enlarged, and neither uterus nor tubes showing signs of previous rupture. The uterus was retroverted and had been pressed against the posterior abdominal wall by the developing foetus. Both ovaries were slightly enlarged. The peritoneal cavity was swabbed dry, all bleeding controlled, and the abdomen closed without a drain.

The temperature gradually dropped following the operation, and on the tenth day, when the stitches were removed, the temperature and pulse were normal. On the twelfth day after the operation the temperature rose to 100°, and there was a slight serous discharge from the lower end of the wound. On the fourteenth day the lower end of the wound had opened up somewhat, and small bits of placenta came away, following which the temperature again dropped to normal. Similar bits of placental tissue continued to be discharged at irregular intervals for a further period of two weeks, following which the sinus steadily reduced in size, and eventually healed. The patient was discharged well on June 5th. Since the date of discharge E. B. has reported herself on many occasions, and at the present time she is engaged in her usual domestic and agricultural pursuits, and feels quite well.

MULTIPLE PERIPHERAL NEURITIS AS A COMPLICATION OF MEASLES

Despite the fact that the complications of measles, and more particularly those affecting the nervous system, are notoriously polymorphic, I have been unable to find in a fairly exhaustive literature any but a passing reference to the occurrence of multiple peripheral neuritis as a complication of this fever.

Three months ago I was called in to attend an adult male who, fifteen days previously, had been in contact with a case of measles. The patient was of good physique, a total abstainer, and had never had measles before. His temperature, catarrhal symptoms, and rash left no doubt that I was dealing with a case of measles of moderate severity on the fourth or fifth day of the disease. On the seventh evening of the disease the patient was restless, complained of pain in his feet and legs, and, on attempting to get out of bed, discovered that his knees would not support him. His temperature was 99.6°, round which level it remained during the rest of his illness. Loss of power in the legs and feet was marked, and neither the ankle- nor the knee-jerks could be elicited. Search was then made for any concomitant diphtheritic infection, but no clinical or bacteriological evidence of this infection was forthcoming.

On the ninth day of the disease the paresis had spread to the arms, and pain of a tingling "pins-and-needles" character became a marked feature in all the limbs, and eventually necessitated the administration of morphine for its control. Tactile sensibility and sense of heat and cold were both slightly impaired in the affected parts. On the tenth day of the disease weakness of the facial muscles was evident, and in twenty-four hours the rare clinical picture of a double

facial paralysis of the peripheral type was fully developed. About this time it was also noted that liquids were being regurgitated through the nose, and a paresis of the soft palate was revealed. On the twelfth day a right-sided external oblique paralysis was detected, and it was also noted that the respirations were hurried and grunting in type, although both the diaphragm and the intercostal muscles appeared to be acting fairly well. There was no sign of any pulmonary complication.

The patient's full consciousness was maintained throughout, and there was no sign of any paralysis of the sphincters. Pain became even more difficult to control in the affected parts, as the choice of drugs had to be limited to those which would not further embarrass the man's vital centres. In view of this parlous state it was decided to administer 30 c.cm. of serum obtained from a convalescent measles patient. This was accordingly done. On the day following the injection the temperature fell to normal and the general condition of the patient was perceptibly better. On this day also it may be noted that the patient's son developed measles, which ran its usual course. On the fifteenth day the facial paralysis had definitely improved, and during the following week the various paralyses began to clear up from above downward at a remarkable rate, till at the end of ten weeks all signs, with the exception of slight diminution of both knee-jerks, had vanished. By the end of the twelfth week no abnormal signs could be detected, and freedom from pain and tingling was complete.

The question, of course, arises as to whether the administration of the serum produced the consequent benefit in this case. While I hesitate to detract from the value of Nature's wonderful store-cupboard of remedies, I, from a purely clinical standpoint, cannot but feel that some of the benefit produced in this case—in particular the fall in temperature—must be attributed to the serum.

Shrewsbury.

D. A. URQUHART, M.B., CH.B.

A CASE OF GASTRIC NEOPLASM: GASTRECTOMY

Among points of rather special interest in the case reported below perhaps the most unusual is the fact that the patient presented himself to his doctor after discovering a "lump" in his abdomen and, when seen later, himself suggested the diagnosis of a cancer of the stomach.

The patient, aged 38, a man of rather unusual intellectual attainments, was referred by his doctor for an abdominal tumour. The history given was that he had suffered from a weak stomach since a child, but latterly the disturbance of flatulence had become accentuated and more persistent than formerly. His appetite was impaired, and he complained of periods of mild upper abdominal discomfort. He had not at any time suffered pain, and consulted his doctor on discovering a lump. Examination disclosed the presence of a movable, irregular mass, descending from under the left costal margin. There was a history of war-period dysentery: other examinations were negative. X-ray examination showed a filling defect of the stomach, with delay in emptying.

Laparotomy, with a right paramedian incision, revealed a growth of the pyloric end extending on to the body of the stomach. The subpyloric glands were palpable and enlarged. Resection was proceeded with, the duodenum closed, and the jejunum anastomosed to the proximal stomach, as in Moynihan's modification of the Polya-Balfour operation. Recovery ensued.

Of particular interest is the insidious progress, and the fact that a correct diagnosis was made by the patient himself. The case well illustrates the dominant and, indeed, often the only, feature of early gastric carcinoma—the disturbances associated with flatulence. Sections of removed stomach showed a glandular carcinoma, with extensive invasion of the muscle coats. The pyloric glands, on section, were found to be infiltrated with new growth.

Reviews

FRACTURES AND DISLOCATIONS

Textbooks on these subjects are too apt to follow a stereotyped form in which all the best-known and typical lesions are described, and the best-known methods of treatment indicated, including, of course, those introduced or favoured by the authors. The practitioner confronted with one of the rarer injuries will probably not consult in vain a recent work on *The Management of Fractures, Dislocations and Sprains*.¹ The authors have flung their net wide, but have not retained the whole catch. Recognizing that fractures of the skull must often involve injuries to the encephalon, they enlisted the services of the late Dr. Charles E. Dowman, a specialist in the discussion of those injuries. Likewise Dr. James Barrett Brown of St. Louis is responsible for the chapter on fractures of the bones of the face and jaws, the treatment of which requires so much familiarity with special measures.

In their preface the authors, Dr. J. A. KEY of St. Louis and Dr. H. E. CONWELL of Birmingham, Alabama, point out that all cases cannot be treated at once by specialists, and that therefore the general practitioner should at least know what is the appropriate emergency treatment for every fracture, and be prepared to improvise and apply it. The necessary equipment for fracture treatment in a hospital of 100 to 200 beds is described, and considerable stress is laid on the advisability of making one officer responsible for the care of the splint room and its contents. This room should be kept under lock and key. For emergency treatment the authors appreciate the value of the Thomas splints, but make the rather surprising statement that these are seldom available, and therefore they recommend preferably extempore board splints, consisting of two longitudinal and three transverse strips of wood nailed and screwed together. Among the complications of fracture and fracture treatment fat embolism is discussed, but only as a rare complication, under which most British surgeons will be prepared to place it. Another more rare complication is the acute traumatic bone atrophy of Sudeck, a case of which is here recorded.

The frequency of road accidents, both in America and in Britain, has made such complications as gas gangrene and tetanus commonplaces of emergency surgery, which before the war were comparatively rare. In the description of the first-named we find a statement that "the patient appears unusually sick." One feature of the disease which has struck surgeons during and since the war has been the state of euphoria, for which, unfortunately, there is no physical justification in such cases. The passing in late years in most States of the Union of Employers' Liability and Workmen's Compensation Acts has made it necessary to include a consideration of medical problems relating thereto in a comprehensive work such as is now under notice. Students of the international aspects of this matter will find on page 169 a useful table of rates of compensation for various mutilations in various States. Fractures of the spine, with and without accompanying trauma of the medulla or nerve roots or trunks, necessarily occupy a large space in this book. It is noteworthy that, in the authors' experience, some half of the cases of fracture are unaccompanied by paralysis. Compression fractures of the spine have lately been attracting much notice, both in Europe and in America. The authors will not be found lacking in attention to this branch of the subject. Its treatment is

¹ *The Management of Fractures, Dislocations and Sprains*. By John Albert Key, B.S., M.D., and H. Earle Conwell, M.D., F.A.C.S. London: H. Kimpton. 1934. (Pp. 1,164; 1,165 figures. 63s. net.)

well set forth. In reference to Kümmell's disease the view is taken that some cases so called are really cases of undetected-compression fracture. When symptoms persist fusion operation after the manner of Hibbs is indicated.

A great deal has been written about low back sprains and backache in the United States of late years, and perhaps more importance has been given to the subject in America than in England. The analysis of 2,050 cases quoted by the authors from the *Journal of Bone and Joint Surgery* is of interest. More than half the cases were attributed to osteo-arthritis and 30 per cent. to atrophic arthritis. In only a small number of cases was fracture implicated. The methods of examination and the manipulations in treatment are very carefully gone into by the authors, who are duly cautious in their conclusions, and do not lose sight of the possibility, or even probability, of malingering and of the important part played by psychological causes in the development of painful back. Part II deals in sixteen chapters with the diagnosis and treatment of specific injuries. Its comprehensive character may be inferred from the inclusion of sprains, overpronated strained foot not being omitted. The authors frankly own up to a difference of opinion in the choice of methods of treatment of extensive compound fractures. It is agreed, however, that "the results are about the same."

We think that the fact that Dr. Key is professor of orthopaedic surgery in Washington University, and that Dr. Conwell is much concerned with the treatment of accidents on a great railway, has broadened their views in several directions, and as a result we have a very comprehensive work to which practitioners will not refer in vain. We only wish that, instead of the one volume weighing six pounds, it were bound up in two volumes.

RELIEF OF PAIN IN CHILDBIRTH

Eighty years ago the question of anaesthesia during childbirth was confused by archaic theological disputations; to-day it has assumed political proportions, to the no small disadvantage of the patient. Dr. F. NEON REYNOLDS has written a clear, concise, and eminently sane account of the present position in a small book entitled *The Relief of Pain in Childbirth*.² The first chapter is introductory, and the second, dealing with the treatment of morning sickness and other minor ailments of pregnancy, is sketchy and out of place. The remainder of the book has to do with the various forms of anaesthesia and analgesia used during the first and second stages of labour. Dr. Reynolds concludes that paraldehyde given per rectum, preceded in the case of a primigravida by a preliminary injection of morphine and scopolamine (spelt "scopolamine" throughout the book), is the best method of relieving pain during the first stage of labour which is available for general use. He believes that there is no risk of proctitis if the paraldehyde is mixed with olive oil, but fails to draw particular attention to the fact that the paraldehyde must be fresh. At least one case of sloughing of the rectum necessitating a colostomy has been reported following the use of "decomposing" paraldehyde. For the second stage of labour Dr. Reynolds recommends either chloroform given through a Junker inhaler or gas and oxygen, if a skilled anaesthetist is present. He disapproves of the use of chloroform capsules (used during the late war and reintroduced for use in obstetrics) by midwives, but suggests that they should be permitted to give paraldehyde during the first stage of labour.

Dr. Neon Reynolds's book can be recommended to all

² *The Relief of Pain in Childbirth*. By F. Neon Reynolds, M.C.O.G., F.R.C.S. Ed. London: Medical Publications, Ltd. 1934. (Pp. 114. 10s. 6d. net.)

who practise midwifery. Many readers will probably concur in the opinion that the use of scopolamine and paraldehyde by midwives would guarantee the maximum alleviation of suffering that can at present be effected with safety.

CLINICAL CARDIOLOGY

Any book which is obviously the result of a prolonged and careful study of a group of facts as these are observed at the bedside has a claim to notice in the columns of a medical journal. Dr. BRUCE WILLIAMSON's volume entitled *Vital Cardiology*³ falls within this description. The author has enjoyed large clinical opportunities; he has applied his mind to the academic problems of cardiac disorders; he has studied critically methods of treatment; and in some directions he has come to conclusions which differ from current teaching, and even bring this under direct challenge. It would therefore be disappointing were the outcome of all this industry to prove unworthy of attention and consideration. Such a negative result has certainly not happened. On the contrary, the student of cardiac disease, and particularly, perhaps, the experienced practitioner, will find interest in Dr. Williamson's pages, even though the interest is not at all points accompanied by unqualified conviction.

In the choice of his title Dr. Williamson has a double aim. The first is to advocate the interpretation of the evidences of cardiac disease on the basis of physiological and clinical observation, while the second is to reduce to insignificance the value of the instrumental and graphic methods which have become prominent in recent years; these, it is suggested, are not infrequently misleading, make prominent what is essentially secondary and subordinate, and, at the best, have largely had their day. Further, it is urged that the problems of cardiac disorder are not to be solved by isolation of cardiovascular disturbances from the general examination of the patient; and to save cardiology from the "status of a specialty" the intervention of Heaven is prayed in aid.

It is, however, in its positive propositions that Dr. Williamson's book mainly professes its value. Its central doctrine is that only in two directions can the function of the myocardial cells vary—namely, in the rate and in the force of their contraction; that, excluding psychic and other extrinsic causes of excessive cardiac rate, such excess is the first evidence of myocardial failure; and that as rapidity shortens the diastolic interval during which an active coronary circulation is secured, any degree of sustained tachycardia means inevitably progressive deterioration of the value of the cardiac force. From all this it follows that a quickened pulse rate must be an object of earnest inquiry, and that when an obvious explanation cannot be discovered such an event means impending cardiac failure. Particularly is this true when from the clinical history or the physical signs there are reasons for believing that the heart muscle has suffered damage, with an inevitable limitation of the measure of its reserve force; while treatment demands agencies which will reduce a pulse rate that necessarily carries the certainty of increasing disability. A third conclusion is that the recognition of such pulse disturbance before symptoms appear is a therapeutic opportunity which, if properly seized, will avoid or postpone further mischiefs. This central thesis, here stated only in general terms, is applied over the whole field of circulatory disturbances and cardiac disease—irregularities of rhythm, valvular murmurs, paroxysmal tachycardia, bradycardia, heart-block, angina pectoris, blood pressure, dyspnoea, cyanosis,

³ *Vital Cardiology. A New Outlook on the Prevention of Heart Failure*. By Bruce Williamson, M.D., M.R.C.P. Edinburgh: E. and S. Livingstone. 1934. (Pp. 344. 15s., postage 9d.)

and the rest; and in each section, as well as in a special chapter, treatment is discussed in some detail. On one practical measure there will certainly be disagreement—namely, the value of prolonged rest in early evidences of mitral disease; here Dr. Williamson maintains that the customary practice favours the establishment of mitral stenosis and the early development of auricular fibrillation, as shown by the more frequent appearance of these conditions in women rather than in men; and in accordance with the proposition, "Stasis and stenosis are inseparables."

It may fairly be said that there is much repetition in the book, but against this comment it must be recognized that Dr. Williamson is proposing and defending a thesis, and is applying a general principle to a wide and varied field of observation; if he often preaches from the same text it is to emphasize the far-reaching value of his doctrines. Again, it may seem that at times he professes little respect for those whose talk is of murmurs and machines, and who have failed, he suggests, to recognize the truth which he himself has discovered, while upon this discovery he takes to himself no small measure of content. In these directions he may excite some sharp opposition. His capacity for denunciation is illustrated by his description of a particular method of prescribing digitalis as both a "vandalism" and an "anachronism." None the less he has written, not hastily, and out of a large and considered experience, and even if his academic argument is put aside there is much in his book of practical value.

ANATOMY OF OUR FOREFATHERS

Professor JOHN CAMERON's work, *The Skeleton of British Neolithic Man*,⁴ brochures, and partly answers, a number of exceedingly interesting orthopaedic problems. For example, why should the osseous anatomy of the lower limbs possessed by the modern inhabitants of Britain differ so decidedly from that of former inhabitants? The author finds that the change from the older to the newer anatomy took place at, or soon after, Norman times. Down to, and including, Saxon times, Englishmen had platymeric femora, and platynemic tibiae and astragali, which, although unmodern in their markings, have not, so far, received a special name. The Neolithic and Bronze Age inhabitants of Mediterranean lands, Professor Cameron finds, had the same markings in the bones of their lower limbs as had the early inhabitants of Britain. He presumes that these characters of the limb bones are of a functional nature, and that they have disappeared from the limbs of the modern inhabitants of Britain because nowadays we walk, run, and hold ourselves differently from our forebears. Professor Cameron is inclined to seek for an explanation of platymeria, etc., in the rapidity rather than in the degree or kind of muscular action in the prehistoric British. It is to be hoped that orthopaedic surgeons may take up these problems of prehistoric anatomy which our author has expounded so ably.

Some years ago Professor Cameron gave up his chair in Dalhousie University in order that he might complete his investigations into the craniology of human races. Since his return to England he has made full use of the rich collections of human material stored in the Museum of the Royal College of Surgeons of England. The book now published is the first harvest of his leisure. It is one which will be welcomed by all who are interested in the early history (or prehistory) of the British people.

⁴ *The Skeleton of British Neolithic Man. Including a Comparison with that of other Prehistoric Periods and More Modern Times.* By John Cameron, M.D., D.Sc. London: Williams and Norgate, Ltd., 1934. (Pp. 272; 51 figures. 15s. net.)

PSYCHOPATHOLOGY

Dr. WILLIAM BROWN has taken the opportunity afforded by the call for a third edition of his book on *Psychopathology and Psychotherapy*⁵ to submit it to a thorough revision and amplification. The book is not intended to give the reader a systematic survey of the dynamic psychologies; it consists of a number of personal contributions, revealing in a considerable measure the writer's own personal views and methods of treatment. Great stress is laid upon the social possibilities of psychology. The author considers, indeed, that the extent to which psychology develops and admits of practical applications during the next few decades may well decide the fate of civilization, whether intellectual and spiritual progress will continue or mankind will rush down through world war to ruin. He suggests that psychology, working in close alliance with philosophy and true religion, can certainly prevent this. Since this book is intended to appeal to the medical man and the educated layman, it is doubtful if the highly technical and mathematical appendices are very suitably incorporated within its pages.

The second edition of Dr. ERNEST NICOLE's book on *Psychopathology: A Survey of Modern Approaches*⁶ includes numerous additions throughout the text and four new chapters dealing with ethnology, schools of psychology, and applied psychology. The bibliography has been enlarged and brought up to date. The student of psychiatry will find this book most useful, and the call for a new edition shows that it has met a definite need.

Notes on Books

Practical contributions to the art of treatment as this is demanded in daily practice are always welcome, and this particularly when they are based upon the personal experience of the contributors. Such is the character of *Modern Treatment in General Practice*,⁷ issued under the editorship of Mr. CECIL P. G. WAKELEY. Each of the fifty-three chapters is devoted to a particular topic, and each carries the endorsement of a writer who has special experience in the subject to which he has directed his pen. The result is a volume very serviceable and particularly useful as a presentation of modern methods and the application of these to general practice. An interesting feature is the judgement which has directed the choice of contributors; these represent most of the medical schools of the country, and the teaching has thus a catholic quality. As an example of the scope of the book may be mentioned the chapter on head injuries in children, written by the editor.

The importance of physical chemistry in immunity reactions is obvious, and writings which assist in the formation of a conception of the mechanism of these reactions must be valuable. The recent book of Dr. R. DUJARRIC DE LA RIVIERE, *L'Immunité par Mécanisme Physico-Chimique*,⁸ consists, however, only of a series of papers on disconnected aspects of the subject, none of which have been thoroughly studied, and contains little mention of physical chemistry. The most interesting sections are that dealing with the flocculation of antineurococcocal sera in the presence of a mixture of

⁵ *Psychology and Psychotherapy.* By William Brown, D.M., D.Sc., F.R.C.P. Third edition. London: E. Arnold and Co. 1931. (Pp. 252. 12s. 6d. net.)

⁶ *Psychopathology: A Survey of Modern Approaches.* By J. Ernest Nicole, L.M.S.S.A., D.P.M. Second edition, revised and enlarged. London: Baillière, Tindall and Cox. 1934. Pp. 283. 12s. 6d.)

⁷ *Modern Treatment in General Practice.* Edited by Cecil P. G. Wakeley, D.Sc., F.R.C.S. London: Baillière, Tindall and Cox. 1934. (Pp. 426; 16 plates. 10s. 6d.)

⁸ *L'Immunité par Mécanisme Physico-Chimique.* By R. Dujarric de la Rivière. Paris: Masson et Cie. 1934. (Pp. 73; 2 plates. 18 fr.)

tincture of benzoin and an alcoholic extract of meningococci, and that on the adsorption of toxins by red blood corpuscles.

In his pamphlet on *Treatment by Training* Dr. GEBHARDT goes deeply into the physiological theory of physical exercises of all sorts as they affect the different tissues of the human body, and gives an account of the courses of training found useful in treating both invalid and normal subjects at Munich. His pages are designed for the instruction of medical men, trainers, masseurs, and indeed all who may find themselves responsible for physical jerks, so-called, of any description.

Professor HINTZE's *Geography and History of Nutrition*¹⁰ sets out to give the reader an account of the countless foods and diets favoured by members of the human race throughout the world and throughout the ages. The first five chapters summarize what is known to us about the tables kept by the Egyptians, Babylonians, Israelites, Greeks, and Romans in days long gone by; there is

⁹ *Übungsbehandlung*. Von Dr. K. Gebhardt. Jena: Gustav Fischer. 1924. (Pp. 60. RM.2.80.)

¹⁰ *Geographie und Geschichte der Ernährung*. Von Professor K. Hintze. Leipzig: G. Thieme. 1934. (Pp. x + 330. M.21.)

reason to believe that the manufacture of beer from cereal grains was practised in Mesopotamia so long ago as 5000 or even 7000 B.C. Later chapters deal with the history of nutrition in Europe, the North, Asia, Africa, America, and Australasia; it appears that the number of plant species ordinarily used as food is about four thousand, all the world over. The book is, naturally enough, a compilation; Professor Hintze writes clearly, and has made a skilful selection from the very extensive literature of the subject with which he deals. The book should be of interest to all specialists in dietetics.

The French edition of the work on the *Mechanics of the Lungs*,¹¹ by Dr. PARODI of Milan, adapted by Dr. Lefèvre, gives the author's account of this obscure and complicated subject; Parodi argues that the lung is an organ with essentially mechanical functions, and concludes that these functions (which are capable of expression in physical terms) must be taken into account in its treatment when diseased. The practical applications of his views are given in a chapter at the end of the book, which should be in the hands of all interested in the subject with which it deals.

Preparations and Appliances

MODIFIED LA FORCE ADENOTOMIE

Mr. ARTHUR MILLER, F.R.C.S.Ed. (London, W.1), writes: The La Force adenotome is considered by many otologists as a definite advance in adenoidectomy. This instrument engages the adenoid tissue from below upwards without interfering with the mucous membrane of the nasopharynx; the blade is kept away from the mucosa by the difference in the

level of the blade and the sides of the box. The adenotome does not leave any bleeding tags behind and fragments cannot find their way into the larynx. It has, however, one drawback in common with adenoid curettes—namely, that a part of the adenoid tissue may be left in the roof of the nasopharynx; this is largely due to the instrument impinging against the posterior edge of the septum, which prevents the blade from reaching the uppermost portion of the adenoids. To rectify this defect I have had a modification of the adenotome made. As the illustration indicates, there is a recess in the box and blade in this modified adenotome which permits the instrument, when introduced, to lie snugly against the posterior edge of the septum; when closed the blade just protrudes through the recess of the box.

I have used this instrument for some considerable time and claim the following advantages for it: (1) The recess permits the surgeon to be certain that the adenotome, when lying against the septum, is also strictly in the middle line of the nasopharynx, thus avoiding the risk of injuring the Eustachian cushions. (2) The uppermost portion of the adenoid tissue is not left behind, as the recess allows the blade to sever the "root" of the adenoids.

The instrument was made for me by Messrs. Mayer and Phelps of New Cavendish Street, W.1.

CERVICAL BIOPSY PUNCH FORCEPS

Dr. ROLAND H. NATTRASS (resident surgical officer, St. Mary's Hospitals, Manchester), writes: The instrument shown in the accompanying illustration is a cervical biopsy punch forceps, which Messrs. Mayer and Co., London, have made for me.

It is a most useful instrument for removal for biopsy of tissue from cervix of uterus. By means of the male and female blades a piece of cervix large enough for microscopy is completely excised, with clean-cut edge and very little haemorrhage.

A DEVICE FOR THE DEAF

Dr. J. MILLER VINE (Grimsby) writes: To overcome the isolation of a deaf person when alone in a dwelling a device has recently been produced which connects the bell system with the electric light and causes the one to operate the other. This is a small metal box 2½ by 3 by 6 inches, which is attached by flex in ten minutes to both systems, and which, when switched into action, causes, in the daytime, any or all the lights to flash on when any bell push is pressed. By night, when they are on, it makes them flicker in a most noticeable fashion. The apparatus can be used with either alternating current or direct current, and incorporates a small transformer activating the bell system from the general electric system, thus eliminating the still common though old-fashioned wet cells. There is no alteration to the existing lights or bells, and the whole thing can be cut out by another switch. After several months' trial it appears foolproof, and there has been no breakdown. The "gadget," named "sordoviso," is not on the market, but those interested should get into touch with the inventor—A. L. Cianchi, 72, Greencroft Gardens, London, N.W.6—who has had a small number made, and may be able to supply them.

British Medical Journal

CANCER RESEARCH

It is difficult for the onlooker to be patient about cancer research. The disease cancer is so much feared, and the results of treatment are often so disappointing, that it is natural to turn eagerly to look for new knowledge. How much more do we know now than a decade ago? Are the chances for a patient better than they were in the days when we were students? These are the questions that often rise in the doctor's mind, and not infrequently find expression in the correspondence column of medical journals. Perhaps our methods of cancer research are all wrong and we are hunting the thimble in the wrong corner of the room. A salutary corrective for this impatient mood will be found in the eleventh annual report of the British Empire Cancer Campaign.¹ Certainly this does not offer us any news of a cure for cancer or even a simple and universal explanation of its cause, but it furnishes a glimpse of many of our fellow creatures who are giving the best of their brains, and often the best of their lives, to study the cancer problem. After reading of the work in progress, not only in this country, but in all parts of the Empire, no one could say that cancer research was barren. It has not yet produced the rich harvest of our anticipations, but there are many promising shoots springing up, sometimes in unexpected quarters. Not many of these have reached beyond what is encouragingly referred to as the "promising stage," but others are now further advanced and begin to have contact with medical practice.

Of particular interest is the work in progress at the Research Institute of the Cancer Hospital, which has found scope for development along three new lines during the last year. The most interesting of these is the inquiry into the biological effects of the female hormone oestrin. This substance, as is well known, is a product of the ovary, and controls the development of the female characters of other parts of the body. It is closely related to cholesterol and to a less extent to the synthetic cancer-producing compounds isolated by Dr. Kennaway and his assistants. It was natural, therefore, to try the effect of painting solutions of oestrin on to the skin of mice in the same way as is done with carcinogenic hydrocarbons. When this experiment was carried out it resulted in a great enlargement of the prostate with obstruction to the flow of urine and hydronephrosis of the kidney. The changes produced in the prostate gland were very suggestive of the early growth of a tumour, though no claim is made as yet

that anything of the nature of a tumour has been produced. Mr. Burrows has begun an inquiry into the possibility that enlargement of the prostate in man might be due to the action of abnormal amounts of oestrin. It has been known for some time that a small amount of oestrin is present in normal male urine, and the experiments now in progress should decide whether there is any abnormal excretion of oestrin in cases of prostatic disease.

It has often been pointed out that chemicals such as tar, which in the past were the only agents available for the experimental production of cancer, seemed far removed from any agent likely to be acting in human disease. The artificial cancer-producing compounds recently isolated, however, have a somewhat similar molecular structure to substances normally present in the body, and the question is raised whether it may be possible for natural compounds to be converted into cancer-producing compounds by some perversion of a normal chemical process. The natural compounds in question are the sterols, the bile acids, and (as mentioned above) the ovarian hormone: the essential molecular structure of these may now be regarded as established, though details remain to be filled in. All these substances contain a peculiar type of tetracyclic ring system which has not until recently been obtained synthetically. The simplest compound containing this type of ring system has now been synthesized by Cook and Hewitt, and it is hoped that before long it will be possible to produce some of the more complex substances resembling the actual compounds which are present in the body. A third line of development which seems to hold out a very promising prospect is the study of the intermediate products of the transformation of cholesterol into oestrin, and the search for enzymes present in the body which might be able to induce such changes. Here is another example of an inquiry into phenomena which might actually occur in the body. As the report points out, the discovery of the surprising biological effects of oestrin comes most opportunely now that the constitution of this compound is understood.

One has only to turn over the pages of the British Empire Cancer Campaign report to see how many different aspects of the cancer problem are being investigated by workers assisted by the funds of the Campaign. A branch of cancer research work of special interest to practising doctors is that which Dr. Lumsden has been carrying out at the London Hospital. In last year's report it was stated that a number of inoperable cases of human cancer had been treated by inoculation of concentrated antiserum. The results actually obtained by this form of treatment were that in every case except one the tumours lessened in size after inoculation of the concentrated antiserum, but this improvement varied in degree and in duration. Complete disappearance of the malignant growth did not follow in any case. Usually after a month or two the tumour resumed its progress to the inevitable fatal termination. In all cases, however, there was temporary diminution of

¹ British Empire Cancer Campaign, 12, Grosvenor Crescent, S.W.1.

pain, due to lessened pressure upon surrounding nerves. In view of these results it was decided that before treating further cases an intensive attempt should be made to refine and concentrate the antiserum still more effectively. If such improvements can be achieved, and can be shown to be effective in lower animals, a further series of human cases will be treated, but not till then.

During the past year the Garton prize of £500 has been awarded to Dr. H. A. Colwell for his essay on the method of action of radiations on normal and malignant cells, and a précis of Dr. Colwell's essay is published in the report. On the recommendation of the judges an additional prize of £100 was awarded to Dr. F. G. Spear and his associates of the Strangeways Research Laboratory, Cambridge, and a précis of this essay also is included in the report. In his introduction to the report Lord Reading, chairman of the Grand Council of the Campaign, remarks that it has been pointed out by a very great soldier that every battle is divided into three parts—namely, the period of preparation when openings are being sought for and positions secured, the period of struggle when each side tries to break down the other's resistance, and the final period in which the morale of the vanquished breaks down. Lord Reading considers that in the battle against cancer to-day we have entered the second of these stages. It is certainly the case that the resources and support of the British Empire Cancer Campaign have permitted a degree of preparation for the attack which otherwise would not have been possible.

PELLAGRA IN ENGLAND

Some of us look on pellagra as a disease of the Far East, and will be surprised to see that Stannus and Gibson¹ have collected 131 cases of this disease which have been reported in this country. It is of interest that 111 were females and twenty were males, and about fifteen of the cases were recorded in children ranging from infancy upwards. The vast majority came under observation in asylums, because of the mental symptoms present. In 1913² Box reported the cases of two children who were brothers. One of these cases was immediately fatal, and a thorough investigation of the pathological material was made by Sir Frederick Mott³ and reported in the same number of this journal. The microphotographs of the histopathology of pellagra, and the coloured plate of Dr. Box's case, would repay inspection by anyone interested in this subject.

The history of pellagra is interesting as throwing light on the aetiology. In 1763 Casal, the Spaniard, published a treatise on the disease, and attributed it to faulty diet, and a few years later the name pellagra

was given to it by the Italians. At that time it was prevalent in Italy. Its spread throughout Europe can be said to coincide with the introduction of maize into Europe from America, where pellagra has been for many years, and still is, a menace. There seems no doubt, however, that pellagra can occur on diets other than maize, such as rice and millet, and some patients reported upon in the British Isles had never eaten maize. Nevertheless, to quote the Medical Research Council's monograph on vitamins,⁴ p. 177, "It should not be forgotten that pellagra is almost exclusively a maize-eater's disease, and that its occasional appearance amongst a population consuming other cereals attracts attention by its very rarity." It was held, and still is by many workers, that pellagra is due to the consumption of proteins of too low a biological value. Without doubt milk and meat are among the most potent foods in the prevention of the disease. Brewers' yeast gives complete protection, and, as yeast contains very little protein nitrogen, it seemed probable that some other factor was at work. This factor, called PP (pellagra-preventive) was found by Goldberger and Wheeler⁵ to be present in tomato juice, wheat germ, and canned salmon, and to this PP factor the name vitamin B₂ has been given. The therapeutic value of yeast is now beyond any doubt. Next in potency come milk and meat. It is still maintained by some that there is a toxin present in deteriorated maize which is the cause of pellagra, but this theory has still to be justified. To quote once more from the Medical Research Council's report: "It is very interesting to recall that in the last century the French physicians concerned with pellagra directed their efforts mainly to the elimination of maize from the diet of the people. Their campaign was ultimately successful, and the use of maize in France was discontinued. The simultaneous disappearance of pellagra naturally appeared to be a complete justification of the policy."

Mott found in his cases a widespread sclerosis of the cord and brain stem. From his experience he put this down to a chronic toxæmia rather than an inflammatory process. There was chromatolysis of the posterior spinal ganglion cells, as well as the anterior horn cells. The peripheral nerves showed degenerative changes. Since the lesions of the nervous system are so widespread it is not surprising that the clinical picture should vary so enormously. There are three sets of symptoms for which the clinician must look out if he wishes to make an early and accurate diagnosis. First, the skin manifestations which appear in the early spring, and are present on the exposed portions of the body—namely, the face (particularly the forehead), hands, and, in children especially, the knees and dorsum of the feet. These parts of the body appear to be sunburnt, but on closer inspection they are rough, and have a bran-like peeling appearance, or the skin is shiny and glazed. As the summer comes on, the

⁴ Medical Research Council: *Vitamins: A Survey of Present Knowledge*, H.M. Stationery Office, 1932.

⁵ Goldberger and Wheeler: *Public Health Reports*, Washington, xlii, 1299.

condition is intensified, and with it other symptoms appear. The second group associated with this sunburnt appearance are the gastro-intestinal symptoms—a chronic diarrhoea, which fails to respond to simple treatment, causing wasting, and very often a sore mouth and tongue are present in addition. The nervous and mental symptoms complete the picture. Usually the former precede the latter by some months, or even years. There may be difficulty in walking; tremulous movements of the hands, amounting almost to ataxia; and much exaggerated knee-jerks, even spasticity of the legs. Then the mental symptoms may show themselves by simple confusion, the patient being rambling or incoherent, or melancholic, with a tendency to suicide, or unduly elated. Finally occur prostration, cachexia, and death.

The prognosis, up to the present, has been extremely bad in this country. In fact, Stannus and Gibson appear to have the first case in this country from which there has been recovery. This was a girl aged 10 years, and her history is known from the age of a few months. Her diet appeared to have been a normal one. The symptoms occurred first when she was perhaps 2 or 3 years old, and the rash was present each summer from that time, gradually becoming more and more marked. Nervous lesions were widespread and mental symptoms definitely present. The patient ran considerable fever at times, and both skin and gastro-intestinal symptoms were typical of pellagra. After continuous treatment with yeast, from the age of 8 years, for a period of two years, a remarkable improvement occurred. She is now back at school, and although she still shows nervous symptoms the skin and intestinal lesions have completely cleared up, and she seems mentally normal. This case must be contrasted with the two reported by Hutchison and Paterson,⁶ the first of which was that of a girl aged 6 years 10 months, admitted to hospital for loss of walking power and shaking of the limbs, and who had been fed on cornflour as an infant. For nearly three years she had had the typical rash on the face, hands, and knees. The second case was that of a girl of 9 years 10 months, who was admitted for mental deterioration and inability to walk, and who had lived all her life in a suburb of London, like the other child. Examination of the blood, cerebro-spinal fluid, and urine showed no abnormalities cytologically or biochemically. The neurological lesions and mental deterioration in these cases were aggravated by the appearance of sunshine and summer weather. Both children died within a few months of their cases being reported.

Doubtless those in charge of mental institutions throughout the country are much on the watch for such cases. Certainly a paper such as Stannus and Gibson's is of extreme value in bringing the symptoms and treatment of this disease afresh before the profession, and it would occasion no surprise if several further cases were recognized as a result of their paper.

⁶ Hutchison, Robert, and Paterson, Donald: *British Medical Journal*, October 13th, 1923.

NUTRITIONAL ANAEMIA

Few physicians to-day would agree with a statement made in the leading textbook of haematology in 1923 to the effect that "it is obvious that malnutrition must be exceptionally severe and of unusual duration before there is any possibility of anaemia developing."¹ It is now known that 50 per cent. of the adult women and infants in the poorest classes of our cities are anaemic, and studies of various communities have shown how accurately the adequacy of the diet is reflected by the haemoglobin level of the population.^{2,3} Nutritional anaemia also affects man indirectly, on account of the heavy losses sustained through the death of farm animals from this cause, and Professor Stanley Davidson and Dr. Leitch⁴ have been wise to include in one review the chemistry of blood formation and the nutritional anaemias of animals and man. There is still much to be learnt concerning the value of different constituents of the diet in blood formation. Dr. Leitch points out that the essential building-stones of the red cells are those of the organic matrix or stroma, the pigment complex of haemoglobin, iron, and the constituent amino-acids of globin. There does not appear to be any evidence that the materials necessary for the formation of the stroma or of globin are ever lacking, and the injections of amino-acids such as tryptophan and histidine, which have been advised by French haematologists⁵ in cases of intractable anaemia, have found scant support in theory or practice. Little is known of the source of the pigment complex of haemoglobin and similar tissue compounds, but there is evidence to indicate that it is derived from similar complexes in the food. Abnormal metabolism, or excessive loss of porphyrin from the body, such as is found in the rare metabolic disorder porphyrinuria, may interfere with haemoglobin synthesis and lead to severe anaemia. Green vegetables are a valuable source of these pigment complexes. They are also a good source of iron, of which spinach, watercress, and parsley contain especially large amounts. It is of interest to learn of the high iron content of syrup (or molasses) and cocoa, which are recommended as a source of this mineral in cheap human dietaries. But it is still uncertain what proportion of the iron of the various foods is available for blood formation. Although egg yolk contains a relatively large amount of inorganic iron, its haemoglobin-forming power in experimental animals has been found to be small. This is a surprising result in view of the high reputation which egg yolk enjoys as a haemoglobin-forming food in man, and there is need for further investigation of the availability of the iron of different foods by actual observations on man. The role of diet in anaemia is essentially prophylactic, for when frank anaemia develops it is scarcely practicable to repair it by diet alone. Professor Davidson assesses the curative dose of iron given as a ferrous salt at 180 milligrams of metallic iron a day, and Fontes and Thivolle⁵ point out that "to give

⁵ Fontes, G., and Thivolle, L.: *Le Sang*, 1933, vii, 210, 342, and 455.

50 milligrams of iron it would be necessary to condemn the patient to eat every day, for weeks or months, about 3 kilograms of fresh spinach, a treatment which would rapidly end in a complete digestive breakdown." In addition to the raw materials of which the red cells are composed, certain hormones, or catalysts, are necessary if blood formation is to proceed in an orderly way. The active principle of liver extract, and copper, are the most important of these. The chemical composition of the liver principle and the element in the diet from which it is derived are still unknown, but any diet which contains a normal amount of first-class protein will supply sufficient material for its elaboration. The chief differences between the distribution of iron and copper in the food are that, as regards copper, poultry is superior to beef, and that root vegetables have about the same value as leaves and legumes. Of outstandingly high copper content are liver, oysters, chocolate, cocoa, and molasses.

WORLD PREVALENCE OF DIPHTHERIA AND SCARLET FEVER

The March-April issue of the Epidemiological Report of the Health Section of the League of Nations gives an instructive account, illustrated by numerous maps, charts, and tables, of the recent trend of diphtheria and scarlet fever prevalence throughout the world. In most European countries, and non-European countries such as Africa, America, Asia, and Australia, the incidence of diphtheria was rising from 1926 to 1930. It is impossible, however, to say whether this represents a significant trend in the curve of diphtheria or is merely a cyclical variation such as might occur in the usual course of the disease and changes in the proportion of susceptible individuals in the population. The diphtheria mortality, on the other hand, during the period 1923-33 shows a notable decline as compared with the last decennia of the nineteenth century and the beginning of the twentieth. Except in Central and Eastern Europe only a fraction of this decline is attributable to the fall in the birth rate and in the resultant proportion of children in the population. In most countries of Western Europe, the United States, Canada, Australia, and New Zealand the diphtheria case fatality rate appears to have reached a fairly low and steady level, whereas in Central and Eastern Europe it seems to be still fairly high and relatively unstable. The campaign that has been carried on in favour of active immunization since 1923 has not yet affected a large enough proportion of the children or total population of the various countries for the results to be shown in the curves of mortality or morbidity. As regards scarlet fever there was an increase in its incidence in 1932 and 1933 in Great Britain, France, Belgium, Holland, Germany, the Saar Territory, Denmark, Switzerland, Czechoslovakia, Hungary, and Japan, but this rise remained within the limits of the more or less regular fluctuations shown by these countries, and did not apparently change the general tendency of the curve over a period of fifteen or twenty years. On the other hand, a decrease took place in Norway, Rumania, Yugoslavia, and Soviet Russia, and the morbidity rate remained more or less stationary in Finland, Lithuania, Austria, Poland, Greece, Turkey, Australia, and the United States. The general decline

during the last ten years, especially in the countries of Northern, Western, and Central Europe, is in the main attributable to a progressive drop in the case fatality and only in an insignificant degree to improvement in the notification of cases. On the other hand, the case fatality remains high in the countries of Eastern Europe, where the mortality is still high and unstable; in other words, where the disease is still prevalent in the epidemic rather than in the endemo-sporadic form.

FRACTURES OF THE NECK OF THE FEMUR

Whitman's method for the treatment of fractures of the neck of the femur has held the field for a number of years; when introduced, it marked a great advance on everything that had gone before. Nevertheless, expressions of dissatisfaction have been voiced more recently, as it has become evident that even this method did not yield more than 50 or 60 per cent. of successes. Another cause for complaint was the danger to old people of long confinement in plaster-of-Paris. Open operation and fixation of the fracture by an autogenous bone graft (Albee, Noordenbos, and others) or by means of a steel pin (Smith-Petersen) is now being practised by a number of surgeons who claim far more frequent successes than were ever obtained by Whitman's method. At this time, therefore, which may well be a turning-point in our attitude towards the treatment of these difficult fractures, a statistical study based on the results of treatment in 250 cases, most of them dealt with by Whitman's method, is of particular value.¹ MacAusland, MacAusland, and Lee confirm the traditional British teaching that this type of injury occurs most commonly in patients past middle life; they find this as true of trochanteric as of cervical fractures. Noordenbos's emphatic statement that such fractures are equally common in young people probably holds good only for Amsterdam, where about half the population live on bicycles, falls from which are by no means unusual. Dealing first with fresh fractures of the femoral neck the authors affirm that Whitman's technique of reduction of the fracture by abduction and internal rotation of the lower limb under anaesthesia, followed by prolonged fixation in plaster in this position, is still the most reliable general method of treatment. In their hands about 60 per cent. of patients so treated obtained a stable painless joint, with an almost normal range of movement; 20 per cent. were able to walk with or without the aid of a stick, though complaining of pain or limp after much exercise; and in the remaining 20 per cent. the results were poor. Almost all the failures occurred in patients over the age of 60. Unlike other simple fractures, fractures of the femoral neck carry a very definite mortality: 7 per cent. of the patients dealt with at the MacAusland clinic died of pneumonia within a few weeks of the injury. When one considers the advanced age and poor physical state of the majority of patients coming to hospital with this condition it must be admitted that these results are impressive. Furthermore, the difficulties of open operation are formidable to all but experienced surgeons: Whitman's method, though not foolproof, is simple by comparison, and this bears out the contention that the latter is the best therapeutic measure for the average case in the hands of the average

¹ *Surg., Gynecol. and Obstet.*, 1934, lviii, 679.

surgeon. Indeed, Whitman's technique may well hold its own against open operation as practised by the specialist until equally extensive statistics have been produced to prove the superiority of the major procedure. If non-union is present, even in spite of efficient treatment by Whitman's method, open operation offers the only prospect of obtaining bony union. At the MacAusland clinic cases of non-union have been dealt with by removal of the great trochanter, followed by insertion of the freshened femoral neck into the head and replacement of the trochanter as low down the shaft as possible. In other cases, in which the head was so atrophic as to be functionally useless, Whitman's reconstruction operation was performed. The authors express themselves as satisfied with the results.

SEPARATION OF RABIES VIRUS FROM BRAIN TISSUE

The electric charge carried by bacteria and filterable viruses has been studied by many workers. Its importance in the agglutination reaction is well known, but attempts to make use of it for other purposes, such as the distinction of virulent from non-virulent bacilli of the same species, have not so far proved very successful. It is probable, therefore, that the results described by Dr. G. Sankaran, Major K. R. K. Iyengar, and Mr. W. A. Beer¹ on the separation of fixed rabies virus from the infected rabbit brain by electrophoresis will arouse considerable interest. Briefly, the experiments consisted in passing a 4-milliamper current through a 5 per cent. suspension of infected rabbit brain in sheep serum, and subsequent testing by animal inoculation of the material collected at the positive and negative poles. The current was transmitted through special electrophoresis cells filled with phosphate buffer solution at pH 7.38. Within thirty minutes of the passage of the current a faint turbidity became noticeable in the side-arm of the cell attached to the positive pole. The level of the turbid fluid continued to rise, and within two and a half to four and a half hours sufficient material had collected to be used for inoculation purposes. The buffer solution in the side-arm of the cell attached to the negative pole remained clear. Six experiments were performed in all, and in each experiment 0.2 c.cm. of the material collected at the positive and negative electrodes was inoculated separately into two rabbits. The results were very striking. Of the twelve animals injected subdurally with the "negative" material, none developed rabies within a month: of the twelve inoculated with the "positive" material all developed typical rabies within seven to nine days—the usual incubation period of the strain of fixed virus used. The conclusion was therefore drawn that under the influence of the current, electro-negatively charged particles had migrated into the positive cell, and that these particles actually consisted of the rabies virus. Further experiments to confirm these initial findings were carried out by Sir Robert McCarrison, Dr. Sankaran, and Mr. Beer.² It was first ascertained that neither normal rabbit brain nor normal sheep serum yielded, on electrophoresis, substances capable of causing rabies-like symptoms in rabbits. It was next shown that street virus from rabid dogs, when subjected to electrophoresis, migrated

to the positive pole, and that material from this pole gave rise on subdural injection into guinea-pigs to rabies in from eleven to sixteen days. The nature of the disease was proved by the demonstration of Negri bodies in the hippocampus. The original experiments with fixed virus were then repeated. Of twenty-eight rabbits and five sheep inoculated with material from the positive pole in ten different experiments, all but two rabbits and one sheep developed rabies, whereas of a similar group of animals inoculated with material from the negative pole none developed rabies. By attaching an L3 filter candle to the lower end of the side-arm of the positive electrophoresis cell, it was found possible to separate the rabies virus elements from the accompanying brain tissue. After passage of the current for twenty-four hours the material inside the filter candle proved infective. Since the material obtained by electrophoresis remains virulent for at least eight days at room temperature, the authors conclude that the way is now open for the preparation of a more highly concentrated antirabic vaccine than has hitherto proved possible.

HARVEY AND LITERATURE

In a recent communication before the History Section of the Royal Society of Medicine (June, 1934, xxvii, 1095) on the subject of "William Harvey's Knowledge of Literature—Classical, Mediaeval, Renaissance, and Contemporary," Professor D. F. Fraser-Harris displays the fruit of a research which should be of interest to students of medical history. In his published writings and in his correspondence Harvey shows the most intimate knowledge of the works of many authors, mentioning twenty-five Greek and fourteen Latin writers and thirty-two names in the Renaissance and contemporary period. In quoting Aristotle so frequently (269 times), Harvey was but following his own counsel contained in a conversation with Aubrey: "Go to the fountain head and read Aristotle, Cicero, and Avicenna." While the majority of references are to subjects of biological importance, he was fond of quoting from Virgil. The absence from this collection of Caesalpinus's name is significant, and Professor Fraser-Harris infers that Harvey found nothing of value concerning the problem of the circulation in the writings of a man who in some quarters even to-day is regarded as its discoverer.

EXCRETION BY THE MILK

There is a vast amount of folk-lore on the excretion of substances into milk, but there is a singular lack of definite scientific evidence as to the substances which actually pass from the maternal circulation into human milk. Recently, Dr. G. Drefus-Sée¹ has made an interesting summary of present knowledge on this question. As he points out, much more is known about the passage of food substances and drugs into the milk of the cow; but it is unsafe to assume that facts established for one species will be true in the case of another. For example, an increase in the salt content of the diet does not raise the chloride content of the cow's milk, but apparently such an effect can be produced in women. A large number of inorganic substances such as bromides, iodides, arsenic, mercury,

¹ *Indian Journ. Med. Research*, 1934, xxi, 909.

² *Ibid.*, 1934, xxi, 917.

¹ *Rev. de Méd.*, 1934, li, 198.

and lead are excreted in the maternal milk, as well as, in traces, a number of organic drugs—for example, anaesthetics and hypnotics, morphine, and many alkaloids such as quinine, caffeine, and strychnine. Other drugs, such as the volatile oils, can change the taste of the milk, whilst rhubarb causes a yellow discoloration. It is, however, doubtful whether the active purgative principles of any of the anthracene group are excreted. It is of interest to note that only very small quantities of alcohol and nicotine find their way into the milk. Dr. Drefus-Sée considers that it is very doubtful whether any drug appears in the milk in a quantity sufficient to produce a definite therapeutic action on the child, and that in all cases drugs and toxic substances are excreted in very small quantities except when there is a massive maternal intoxication.

BIOCHEMISTRY AND NUTRITION

The council of the Royal Society of Arts attended at Clarence House on July 11th, when the president, H.R.H. the Duke of Connaught, handed the Society's Albert Medal for 1934 to Sir Frederick Gowland Hopkins, P.R.S., "for his researches in biochemistry and the constituents of foods." In making the presentation the Duke of Connaught said: "Your work has largely lain in the domain of pure biochemistry. Your discoveries have not only enriched this science, but have done much to make it a distinctive subject for study, attracting a large and enthusiastic body of research workers. Actually the discovery that foodstuffs contained certain factors now called vitamins, and that life could not be maintained on a synthetic diet alone, gave a new impetus to work on nutrition and to the study of deficiency diseases, in which work you have continued to take an active part. In consequence the world has acquired a clear conception of the vitamins, of the part they play in health and disease, and their distribution in various foods. As a further result, nutrition, the feeding of a nation, is becoming a more exact science, to the benefit of the health of everyone. Of no less consequence to the general advance of science has been your personal willingness at no small sacrifice of comfort and leisure to give help at all times and in every way to scientific workers and associations with scientific aims. I have the greatest pleasure in handing you this medal, which was founded as a memorial to my dear father in 1862."

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* and *Epitome* have been printed; they will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or all of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

On March 4th, 1935, Sir Holburt Waring, President of the Royal College of Surgeons of England, will open the new building of the Royal Australasian College of Surgeons, in Collins Street, Melbourne.

ROYAL COLLEGE OF SURGEONS CONVERSAZIONE

EXHIBITIONS AND DEMONSTRATIONS

Those who attended the conversazione of the Royal College of Surgeons of England, on July 11th, were entertained by a series of interesting demonstrations and exhibitions of the latest work in surgery and in cancer research. Developments of new technical methods were shown by research workers at the Buckston Browne Surgical Research Farm and at the Royal College of Surgeons Laboratories. These included a new treatment for spasm of the cardiac sphincter, and a method for resection and anastomosis of the lower third of the oesophagus. The results of treatment of facial paralysis in man by autogenous grafts and the experiments which led to the development of this treatment were illustrated by cinematograph films. A most interesting exhibit was an experimental study of surgical shock, which demonstrated that it is no longer possible to hold to the theory that shock depends on the distribution by the blood stream of histamine or other products of tissue trauma. From these experiments a possible line of treatment was suggested. The Surgical Unit of St. Bartholomew's Hospital demonstrated some of the results of arteriography in diseases of the peripheral vessels. Thorotrast injections were used and radiograms taken at definite times after the injection. The results of thoracic ganglionectomy for Raynaud's disease and of radium treatment for carcinoma of the tongue were very strikingly shown by water-colour drawings. Studies of diaphragmatic herniae and hyperparathyroidism in relation to bone conditions were also demonstrated.

RECENT WORK ON CANCER

The series of exhibits bearing on the cancer problem was most complete. Tissue culture work was demonstrated by the Strangeways Research Laboratory and the Stroud Laboratories of the Imperial Cancer Research Fund. The former institution showed the effects of gamma rays in known doses on isolated cells *in vitro* and on the whole embryo. The effects on the whole embryo were of great interest, as it was shown that gamma rays have two effects—a direct one on the cells, and an indirect one on the cells due to damage of the circulatory system. The growth and spread of "filterable" fowl tumours were demonstrated by the Stroud Laboratories, which also exhibited an interesting series of specimens and photographs of individual cells after various experimental procedures. A method of differentiating cells in tissue cultures by means of vital staining was used also to determine the functional activity of the cells.

The exhibit of the Imperial Cancer Research Fund Laboratories included a demonstration of the technique of micro-incineration, which eliminates the organic matter in the section and enables the mineral skeleton to be examined and the relative increase or decrease of the inorganic salts to be determined. Experimental work on cancer-accelerating substances found in the liver has shown that these substances are not identical with the haemopoietic factor. It was pointed out that it is not yet known whether or not the cancer-accelerating substance is present in the many preparations of liver on the market, or if the administration of fresh liver in pernicious anaemia cases is likely to precipitate the onset of cancer in susceptible individuals. The division of spontaneous tumours into radio-resistant and radio-sensitive groups was shown. It appeared that in the radio-sensitive tumours there is no direct lethal effect on the malignant cells, but that the effect produced by radiation is due to

an invasion of macrophages, which are later transformed into fibroblasts. In this way a massive stroma is formed and the tumour split into narrow strands of cells which are absorbed later. There is no macrophage invasion in the radio-resistant tumours and consequently no stroma formation. The importance of these observations, in view of the extensive use of radium, cannot be gainsaid, but it will be necessary to reconcile these results with the known direct and indirect effects of radiation on growing cells such as was demonstrated by the Strangeways Research Laboratory.

The Research Institute of the Cancer Hospital and the Research Laboratories of the Middlesex Hospital combined to demonstrate the effects of cancer-producing compounds closely related to oestrin. It was shown that these substances are capable of producing a full oestrous response in addition to producing cancer when applied to the skin. Oestrin in benzene solution painted on the interscapular region was found to produce mammary cancer in a castrated male mouse within 175 days from the commencement of the application to the skin. The transmission of tar-induced tumours in the fowl by filtered extracts was demonstrated by the Middlesex Hospital. The interpretation of this result will provide much interesting discussion on the relation of a virus to the tar-induced tumours.

The Physics Department of St. Bartholomew's Hospital contributed an interesting series of experiments illustrating the effects of radiation on chemical activity and on colloids. An ingenious radiation detector was demonstrated. This piece of apparatus was able to detect amounts of radium salts which were too small to be seen or even to affect an electroscope. The application of very high frequency electrical currents to the differential healing of tissues was shown. This machine will make it possible to heat a specific tissue to any temperature, while other tissues surrounding it remain at body temperature. It is possible, with this apparatus, to "boil" an egg in water without heating the water or without any electrical contact being made with either egg or water! Will it be possible, some day, to "cook" a cancer without affecting the normal tissues? Perhaps an answer to this question will not be long delayed. Professor J. C. McLennan of the Radium Beam Therapy Research at the Radium Institute gave a demonstration of the use of the 5-gram unit. Methods of detection and measurement of radiation and the effective screening of large masses of radium were demonstrated.

OTHER SCIENTIFIC EXHIBITS

In addition to the above demonstrations bearing directly on surgical advances and cancer research there were many other scientific exhibits. The National Institute of Medical Research contributed two demonstrations: (1) A demonstration of the actions of acetylcholine. (This substance is released at parasympathetic nerve endings in ganglia and at the endings of voluntary nerve fibres on striped muscle, and has, therefore, an important role in the animal economy.) (2) The recent work on viruses was also demonstrated. "Virus bodies" or "inclusion bodies" were demonstrated from various kinds of tissue. The application of the tissue culture technique to the study of scar formation on the chemical factors involved in the process of repair formed part of the Strangeways Laboratory exhibit.

Experimental work on teratomata and the analysis of the tissues of these tumours was shown in the Buckston Browne Surgical Research Farm exhibit. A study of these tumours demonstrated the fact that certain tissues are always differentiated in close association to each other—for example, nerve tissue always close to cartilage and

bone. Connexions of the brain cortex with different parts of the thalamus and the connexions of the retina with specific regions in the lateral geniculate body formed the demonstration of the Anatomy Department, St. Thomas's Hospital.

Two anthropological demonstrations completed the exhibition. The first consisted of the ancient human remains found in caves on Mount Carmel in Palestine by a joint expedition led by Miss Dorothy Garrod. The specimens included the Neanderthaloid skeletal remains now being freed at the Royal College of Surgeons from the rocky matrix in which they were embedded. A very much earlier fragment of a human femur and specimens of the modern type of man from the upper levels of the caves were shown. The second exhibit was a museum case to illustrate the discovery of Piltdown man. A scale model of the site showed the exact situation in which were found the jaw and occipital fragments. The model was finished with actual specimens of the gravel layers. Casts and reconstructions completed a very interesting exhibit. This case is but the first of a series which will illustrate the most historic sites where relics of ancient man have been found.

The guests were received in the museum hall by the President and Lady Waring. Dr. J. A. Murray and Professor J. C. McLennan gave their demonstrations in the lecture theatre. In the inner hall books and manuscripts from the library were on view. This was the first medical scientific evening of the kind that has been held at the College, and the general hope is that it will not be the last.

STUDY OF CHRONIC RHEUMATISM

AN INTERNATIONAL CONGRESS

An international congress devoted to the study of chronic rheumatism was held at Aix-les-Bains in Savoy from June 28th to July 1st, under the presidency of Professor Fernand Bezançon of Paris. Some 350 medical men attended, and official delegates were present from twenty countries.

The subject chosen for discussion was "Rhumatisme Chronique Progressif Généralisé," or, as we know it, rheumatoid arthritis. During the meeting twenty papers and some forty short communications were read. The work was arranged so that the first day was devoted to a general survey of the problem and to the pathology and aetiology of this disease process. On the second day the clinical aspect was discussed, with special reference to symptomatology and to clinical diagnosis. The third day was devoted to therapeutics.

GENERAL SURVEY OF RHEUMATOID ARTHRITIS

Professor Bezançon and Dr. Mathieu-Pierre Weil of the Saint-Antoine Hospital in Paris defined the limits of this subject, and described in detail that clinical picture which was originally presented by Charcot and which is recognized in this country as "rheumatoid arthritis." Subsequent speakers, including Professor Mouriquand of Lyons and Professor Roche of Geneva, discussed the relation of endocrine factors, infection, constitution, and the autonomic nervous system to the disease. Professor F. Coste (Paris) gave a critical review of the evidence on which the various theories of infection have been based, and assessed the relative value of the work that has been done in connexion in particular with the streptococcus, the gonococcus, and the tubercle bacillus.

As might be expected from the international character of the meeting, terminology was used somewhat loosely, and a great variety of different conditions were referred to under the title of rheumatoid arthritis. The general trend of thought, however, was undoubtedly towards the French

concept of "arthritis," to the individual and the way he reacts, on account possibly of a specific constitution or diathesis, to a variety of extraneous factors, such as infection, metabolic disturbance, and so on, to produce the clinical picture of rheumatoid arthritis. This aspect was emphasized frequently in contradistinction to a specific infection or metabolic upset being the specific cause of the clinical pictures presented by this disease.

CLINICAL AND PATHOLOGICAL ASPECTS

The second session opened with a paper by Dr. Francis Bach (London) on the anatomy and the physiology of the skeletal system, and the pathological changes that occur in the early stages of rheumatoid arthritis. The importance of the general decalcification of bone, as one of the earliest signs of this disease, was emphasized by Dr. S. Gilbert Scott (London), who followed with an interesting paper on the radiographic aspect of rheumatoid arthritis. The bone changes that may be present in the various stages of the disease were described, and an illustration was given of the value of the standardized radiograph of the hand as an aid to the early diagnosis of rheumatoid arthritis, and its differential diagnosis from osteoarthritis, gout, and other conditions. Professor Abrami (Paris) gave an able word picture of the different clinical forms in which the disease may manifest itself, and Professor Marañón (Madrid) read a carefully prepared paper on the differential diagnosis of rheumatoid arthritis. Drs. R. J. Weissenbach (Paris) and F. Françon (Aix-les-Bains) discussed the importance of taking, in conjunction with the clinical picture, the laboratory and the radiographic evidence and the response to treatment in making a prognosis in the individual case. A paper on sulphur metabolism in rheumatoid arthritis was communicated by Dr. A. R. Neligan and Mr. H. B. Salt, M.Sc., from the laboratory of the Royal Bath Baths Clinic, Droitwich. The session concluded with a paper by Professor Kahlmeter (Stockholm) on the changes in the blood which may be found in this disease.

DISCUSSION ON TREATMENT

The third session was devoted to a discussion on treatment. Among the papers was one read by Sir William Willcox, who discussed the part that infection, and in particular "focal" infection, plays in the genesis of this disease. He outlined the technique of its treatment by vaccine therapy. Professor Rathery (Paris) described the methods of drug treatment and chemotherapy that have been recognized to be of value. Professor Gunzburg (Brussels) described the indications for, and the methods of, physiotherapy that may be applied. Professor Paul Mathieu, professor of clinical surgery in Paris, and Dr. Loring T. Swaim of Boston described the orthopaedic treatment of rheumatoid arthritis. A provocative paper was read by Professor Leriche (Strasbourg) on the role of surgery in this disease. He described bone and joint pathology, and the role of the parathyroid gland in the regulation of calcium metabolism. He stressed the value of parathyroidectomy in the treatment of this disease, and discussed the indications for arterial sympathectomy and arthroplasty. A film showing aspects of the orthopaedic treatment of rheumatoid arthritis was demonstrated by Dr. Vincent Coates (Bath).

Most of the papers read at the meeting were collected and published beforehand.¹ The secretaries, Dr. Mathieu-Pierre Weil of Paris and Drs. F. Françon and J. Forestier of Aix-les-Bains, had arranged the scientific part of the congress with great care. The subject for discussion had been well defined, and excellent opportunities were given for the consideration of its pathological, aetiological, and clinical aspects. The new thermal baths were open for inspection, and the various methods of physical treatment for which Aix-les-Bains has long been famous were shown to the delegates.

BEIT MEMORIAL TRUST FOR MEDICAL RESEARCH

A meeting of the trustees of the Beit Memorial Fellowships for Medical Research was held on July 12th for the election of Fellows and other business. The annual report, which was adopted by the trustees, expressed deep regret at the death, on July 3rd, at the age of 82, of their senior colleague, Sir James Kingston Fowler. For twenty-one years, in his double capacity of trustee and honorary secretary, Sir James had given devoted service to the welfare of the Trust, and when enfeebled health made it necessary for him to relinquish the secretarial duties he still watched closely, as trustee, the progress of the work, which owed so much of its success and even of its existence to his creative powers. When Dean of the Faculty of Medicine in the University of London Sir James had been foremost among those who were planning for certain changes in the teaching of the preclinical subjects, and for this end he had won the practical sympathy of Mr. Alfred Beit. The plan was not realized, but Sir Otto Beit, on the death of his brother, generously decided to give the money that the latter had intended for the plan, together with a great addition to the sum on his own part, for a new purpose—the establishment of Beit Memorial Fellowships. The Trust was created in 1909, and every step of its formation and growth was nursed by Sir James with a wisdom that rested on his knowledge of practical affairs, and yet never lacked the vision that was content to wait for results provided that Fellows of high scientific abilities were chosen. His eager care in fostering the aims of the Trust rivalled that of the founder himself—Sir Otto Beit—during the twenty years in which the latter lived to preside as chairman of the trustees; and to both of them (now dead) all gratitude is due for such personal service.

Fellowships throughout the year 1933-4 were held by twenty-four workers. Among the distinctions gained by past and present Fellows during the year may be especially noted the appointment of Professor E. Mellanby, F.R.S. (1910-12), as secretary of the Medical Research Council. Dr. H. Cohen (1924-5) has been appointed Professor of medicine in the University of Liverpool. Dr. Helen Mackay (1920-2) was elected to the Fellowship of the Royal College of Physicians, London, being the first woman to be thus honoured. Dr. Dorothy Russell (1923-6) gained the Hunter Medal and Triennial Prize of the Royal College of Surgeons, London; and Dr. Janet Vaughan (1931-4) received the Triennial Liddle Prize of the London Hospital. Dr. Maurice Stacey (1933-) earned an unusual distinction as first-year Fellow in being awarded the Meldola Prize of the Institute of Chemistry.

ELECTION OF NEW FELLOWS

The following elections to Fellowships were made by the trustees:

Fourth-year Fellowships (value £500 per annum).—Robert Hill, M.A.Camb. To continue his research on the properties of haemoglobin and cytochrome. (Dunn Institute of Biochemistry and Molteno Institute, University of Cambridge.) Leonard Hubert Stickland, M.A., Ph.D.Camb. To continue his work on the metabolism of the strictly anaerobic bacteria of the genus *Clostridium*. (Dunn Institute of Biochemistry, University of Cambridge.)

Junior Fellowships (value £400 per annum).—Solly Zuckerman, M.A.Capetown, D.Sc.Lond., M.R.C.S., L.R.C.P. Proposed research: Experimental study in animals of the neurovascular control of reproductive functions. (Department of Human Anatomy, University of Oxford.) Harold Williams Fullerton, M.A., M.B., Ch.B.Aberd. Proposed research: The aetiology and treatment of hypochromic anaemia of women of the poor classes. (Department of Medicine, University of Aberdeen, and the Rowett Research Institute, Aberdeen.) Emanuel Mannie Lourie, M.B., B.S.Lond., D.P.H., D.T.M. and H. Proposed research: Studies on chemotherapy in protozoal disease. (Liverpool School of Tropical Medicine.) Joseph Stanley Mitchell, B.A., M.B., B.Ch.Camb. Proposed research: The effects of radiation on thin protein films.

(Laboratory of Colloid Sciences, University of Cambridge.) David Ezra Green, M.Sc. New York, Ph.D. Camb. Proposed research: The effect of hormones and vitamins upon the metabolism of individual organs. (Institute of Biochemistry, University of Cambridge.) Gordon Allison Grant, M.Sc. Dalhousie, Ph.D. Toronto. Proposed research: The metabolism of galactose and the physiological synthesis of lactose by the active mammary gland. (Lister Institute of Preventive Medicine, London.) Stuart Lawson Cowan, B.Sc. Lond. Proposed research: To continue study of the chemical exchanges occurring in crustacean nerve, as a result of stimulation and oxygen want; to study the blood flow through the kidney during diuresis. (Pharmacology Laboratories, University of Cambridge.) Maurice Jowett, B.Sc., Ph.D. Liverpool. Proposed research: Metabolism of the central nervous system with reference to the effects of narcotic and basic amines in cases of mental disorder. (Biochemical Laboratory, Cardiff City Mental Hospital.)

In considering candidates for election this year the trustees were influenced by a special desire to promote research in relation to mental disease.

All correspondence of Fellows and candidates should be addressed to Professor T. R. Elliott, M.D., F.R.S., honorary secretary, Beit Memorial Fellowships, University College Hospital Medical School, University Street, W.C.I.

Union of South Africa

[FROM OUR CORRESPONDENT IN PRETORIA]

Medical and Nursing Services in the Native Territories

The urgent health needs of the four million Bantus living in the native reserves of the Union are at last to be met by an organized scheme of relief. Six years ago a State commission inquired into the practicability of training Bantus in medicine, with a view to their serving their own people in the territories after qualification. It was then pointed out that there were areas where only one medical man was available to attend to the health needs of some 40,000 people. In such areas native herbalists and witch doctors flourished, and preventable mortality was excessive. That commission recommended that a full course of medical training for natives leading to a registrable qualification be instituted at one of the South African universities. This was considered by the Government of the day to be impracticable, and no action was taken in the matter.

Recommendations of Departmental Committee

Last year an interdepartmental committee was appointed by the Government to advise on methods for meeting the health needs of the Bantus, and during the 1934 Budget debate the Minister of Public Health announced that the Government proposed to carry out the recommendations made by that committee. The committee pointed out that the provision of a sufficient number of fully qualified native practitioners to meet the requirements of all the reserves was impracticable. Even if all financial obstacles could be overcome, the difficulty of providing the necessary training would still be insuperable. The number of suitable Bantu students who would be available for training would of necessity be very small for many years—too small to justify the establishment of a separate Bantu medical school. Parallel classes at the two existing European medical schools would also be unjustifiably expensive, in view of the relatively small number of students who could avail themselves of the course. Individual talented Bantus should not, however, be debarred from all prospect of qualifying as doctors, and the legitimate claims for higher education could not be ignored. Since facilities for their training in the Union could not be provided, although such were provided for

their fellow tax-paying European citizens, some State aid in the form of scholarships for proceeding over-seas was recommended. The inducements for European practitioners to settle in the reserves were too slight to attract more than a very few, apart from the State-aided district surgeons and the devoted men working in conjunction with missionary societies. With full facilities provided the number of Bantus who could qualify during the next few decades would also be much too small to meet the medical requirements of these people.

Medical Aids

Because of the urgent necessity of providing some medical relief, however, special training of suitable natives in a shortened course not leading to a medical qualification was recommended. The individual so trained is to be referred to as a "native medical aid." The course will, at all stages, differ from the corresponding stage of the medical curriculum. Apart from the elimination of study unnecessary to the future activities of the medical aid, it was considered important to meet possible opposition from the medical profession because of an "inferior" medical degree or diploma. The training will differ fundamentally from the medical curriculum in that it will not be concerned with principles on which the practitioner subsequently builds. The medical aid will be trained to do a limited number of duties very well. Thus he will be specially trained in first-aid treatment, and in the careful preparation of blood smears for malaria examination, of nasal smears for leprosy examination, and of sputum for tuberculosis examination. In such matters high technical skill will be required of him. He should be capable of dealing with most of the ordinary ailments and injuries, and know when to call to his aid a medical man. He will be in full-time Government employ, though he may be seconded to a local authority or other body concerned with health administration. Private practice will be precluded. Any fees due by patients for services rendered will be collected by the Government or local authority. He will be given a suitable house, considerably superior to the huts in the kraal where he will be stationed, and a dispensary and consulting room will be provided. The Minister stated that the proposals had been generally approved by the Federal Council of the South African Medical Association, and the Government had decided to accept the obligation of the conduct of a native health service. The institution of the scheme would necessarily be progressive, keeping pace with the training of the necessary personnel. It was contemplated that ultimately 200 native medical aids would be employed, at the cost to the State of approximately £70,000 per annum. The initial capital expenditure for residential and dispensary quarters would be about £100,000. Realizing the importance of the proposed health service, not only for the natives but for South Africa as a whole, the Government has readily accepted these commitments.

The Johannesburg Chamber of Mines had previously announced that it was prepared to make an appropriate donation towards some suitable scheme for Bantu welfare in the Union. On learning of the Government's decision it donated £75,000 for the medical training of natives, the disposal of this sum being left to the Government. The latter decided, with the Chamber's concurrence, to pay it to the South African Native College, the council of which is to be empowered to use not more than £5,000 for building purposes, and to invest the remainder as a permanent fund. As a result of the Chamber's generous action, coupled with the Government's decision, it has now become possible to proceed with one of the biggest forward steps in native welfare which have been taken for a very long time.

Female Nurse Aids

The need for female nurses in the reserves was also emphasized by the committee, and it was proposed to provide facilities for the training of a large number of nurse aids, with special reference to obstetrics. The committee was satisfied that the best way of providing additional native nurses and nurse aids would be by subsidizing to an increased extent the various mission hospitals that are already doing most praiseworthy work in this connexion. Non-European hospitals under provincial government administration should also be induced to increase the training both of registrable Bantu nurses and of nurse aids.

England and Wales

Port Sanitation at Liverpool

A comprehensive survey of the activities of a port sanitary authority, with an indication of the ways in which these activities are related to the local inhabitants and to the general community, is afforded by the annual report of the medical officer of health to the Port Sanitary Authority of Liverpool for 1933. Dr. W. M. Frazer details the measures adopted under the Port Sanitary Regulations, with special references to the campaign against rats, the improvement of the sanitation of vessels, the inspection of imported foodstuffs, and the medical inspection of aliens, interspersing observations on the way in which these measures have worked out in practice. An additional attraction is a review of the development of the Port of Liverpool by Dr. E. R. Peirce, senior assistant port medical officer, since the first reference to it in the reign of Edward III. From 1901 onwards all vessels arriving from abroad have been examined by trained rat-searchers, and many epizootics of rat plague have thus been brought to light. In the year under review no case of bubonic plague was detected. When any possible harbourage for rats is seen, representations are made to the owners or agents, and such harbourage is eliminated or the certificate is endorsed. The Liverpool docks are of solid construction, and for the most part present a minimum of shelter for rats, apart from such places as engineers' stores and accessory structures. As the result of long-continued action these have now been rendered rat-proof, and are so maintained. Dr. Frazer concludes, therefore, that the risk of the introduction into this country of rat plague has now been very greatly reduced. He adds that since the enforcement of Article 28 of the International Sanitary Convention of Paris (1926) there has been a steady increase in the number of ships examined which show no evidence of rat infestation. The methods adopted at Liverpool have proved so successful that numerous inquiries about the details are received. Dr. Frazer has therefore deemed it useful to reproduce in his present report the lines of procedure which were published in its predecessor. Statistics indicate that, in spite of the most careful precautions, rats are always likely to gain access to a vessel when cargo is being loaded. For "deratization" the fumigation of ships with sulphur dioxide or hydrocyanic acid gas is preferred. On one occasion last year a partly loaded vessel had to be fumigated. So far as could be ascertained no damage was done to the cargo, which included sugar, rice, bags of salt, and barrels of port produce. Dead rats were found in various parts of the vessel. Close attention has been paid to the hygiene of the quarters of crews. The use of tongue-and-groove boards in the forecables is the cause of a large amount

of infestation with bugs, and the Port Sanitary Authority always urges that this form of boarding should be removed, with subsequent free use of the blow-lamp. If boards are to be used in the forecable three-ply wood should be substituted. A marked improvement in the condition of the crews' quarters has been noted when they are fumigated for each voyage and sprayed with an insecticide, a supply of which is made available also for use during the voyage. Food inspections have shown that much more care is now being taken to exclude unsatisfactory carcasses in most importing countries, but not yet in all. Exception was taken to the label "Fit for human food" which was carried by one consignment of canned dog food. Such examples of the details of the work of the authority enliven a valuable report.

Sheffield Radium Centre: Deep X-Ray Therapy

On July 5th the Duchess of York opened the Sheffield Radium Centre. In greeting Her Royal Highness on behalf of all associated with the Sheffield Royal Infirmary and the Radium Centre, Sir Ronald Matthews referred to the installation of a new deep x-ray therapy set. Sir Ronald said: "I think, I may say that it has, so far, justified the highest expectations of those who advised us to install it, and I hope that in years to come it will be a means of saving a great deal of suffering among the people of Sheffield and the surrounding areas." The x-ray equipment in the Radium Centre has been supplied by the research department of the Metropolitan-Vickers Electrical Co., Ltd., and the arrangement is such that it is possible to treat two patients simultaneously, but the apparatus is designed so that this is done with a minimum of complications. The equipment, under the control of Dr. F. Ellis, comprises two x-ray tubes and associated apparatus, operating at 200,000 volts. The Metropolitan-Vickers high-voltage x-ray tube for deep-therapy treatment has been rendered possible by the production in the company's laboratories of a range of low vapour pressure oils for use as working fluids in condensation pumps, thus enabling the highest vacua to be attained without the use of liquid air or other cooling media. These pumps had already been applied to evacuate dismountable valves, and experience had been gained of their operation under commercial service conditions. The feasibility of running vacuum apparatus continuously on pumps had been proved many times, and Dr. T. E. Allibone, who had already demonstrated that x-ray tubes operating under laboratory conditions at up to 450,000 volts could be run in this way, was soon able to design a tube suitable for medical service and operating at 200 to 250 kV.

Central Midwives Board

At the July meeting of the Central Midwives Board for England and Wales it was agreed to reply to an inquiry from the county medical officer of health for Hertfordshire that, as the rules stand at present, the administration by midwives of nitrous oxide or, in fact, of any anaesthetic, by any method otherwise than under the direction and personal supervision of a duly qualified medical practitioner, is regarded as treatment outside their province. The following point had been raised by the medical officer of health of a local supervising authority. In his area, he said, there was a nursing association employing a district midwife who did not wish to book abnormal cases, but was required to do so by the association, apparently at the instigation of four doctors on the committee of the association, one or more of whom, it was suggested, would be summoned by the midwife under Rule E. 20 to the abnormal cases, and would thus benefit by the payment of fees by the local supervising authority. The medical officer of health felt that these

cases should be booked by doctors, and that the local supervising authority should not be called upon to pay fees to the doctors because, in the first instance, the case was booked by the midwife and doctors were then summoned under Rule E. 20. He wished to know if he would be justified in telling the midwife that she must not book these abnormal cases. The Board agreed that the medical officer of health had no power to instruct a midwife not to undertake work which, by law, she was entitled to undertake.

India

Health of the Armies in India

The second volume of the annual report of the Public Health Commissioner with the Government of India for 1932 deals with the health of the British and Indian armies in that country. Malaria still remains the chief scourge, 14.5 of all admissions to hospital in the year under review being due to it. Yet there has been a gradual decline in the last decade from an admission rate of 206.8 per mille in 1924 to 84.1 in 1932, when, however, the climatic conditions were generally unfavourable to the spread of malaria. An adverse factor was introduced by the suspension of antimalarial engineering work by the prevailing financial stringency. Partly by a process of exclusion, and partly from slowly accumulating clinical and statistical evidence, the tentative opinion is now expressed that the more extensive and intelligent use of plasmoquine is mainly responsible for the fact that 1932 was a record year. The full results of the first year's systematized administration of the drug are not yet available. In addition to the improvement as regards malaria there were fewer admissions to hospital in 1932 in respect of all the other causes. The combined ratio of constantly sick in hospital and under treatment as out-patients was 47.02 per 1,000 of the strength, compared with 50.71 in the previous year. The actual loss to the army in India in working days was 972,579, as compared with 1,033,607 in 1931. The mortality and invaliding rates were similarly lower. Sandfly fever continues to be a source of anxiety, despite the destruction of breeding places. Certain observations suggest that the infection is not acquired in the barrack rooms so much as during night duty in the trenches guarding the perimeter. Active investigation is being pursued into the habits and bionomics of the sandfly. The admission rate of dengue is diminishing. The diagnosis of sporadic cases of typhus is becoming much more common, probably owing to a more universal recognition of the symptoms of the disease than to an increased incidence, since in the past there is little doubt that many cases were classified as pyrexia of unknown origin. While the general picture corresponded to tick typhus, as described by Megaw and others, it has been impossible in most cases to obtain a definite history of tick bite. There was often a relationship between the onset of the disease and recent residence in forest bungalows and camps, which is in keeping with the hypothesis that typhus is a disease of the wilds, normally occurring in some lower animal which constitutes the reservoir of infection, and conveyed to man by some parasitic arthropod which occasionally selects him as a host. Although there has been a steady decline of the enteric fevers in both the British and the Indian armies, the case mortality has shown little variation in the last few years. Blood culture remains the most satisfactory method of diagnosis. Statistical tables indicate the value of prophylactic inoculation in reducing the incidence of these infections, though it does not influence the case mortality. It is admitted

that these findings are at variance with the generally accepted views. The dysentery and diarrhoea figures remain undiminished. It is believed that the policy of multiplying examinations for carriers had led rather to the concealment of active cases, and it is now proposed to abandon it in favour of a system of encouraging the active bacillary case to report sick and to be suspended from duty until non-infective. Intractable chronic or relapsing cases will be discharged. Examination of possible amoebic carriers has similarly failed. At no time has the incidence in units suggested carrier infection; on the contrary, it has been roughly proportionate to the numbers at risk. Moreover, the number of detected carriers is in excess of the number of cases of amoebic dysentery, and it is concluded, therefore, that the cyst-passer is only one of the factors in infection. Routine investigations for carriers are being abandoned as of inadequate value.

Extension of Madras General Hospital

Sir George Stanley, Governor of Madras, opened, on March 26th, the new institute of radiology, the new surgical block, and the new pathological block of the Madras Medical College; the new out-patient department of the General Hospital has been in use for nearly two years, and is part of the same scheme for hospital extension in Madras which originated when Lord Goschen was Governor. The General Hospital was founded in 1664; it was rebuilt in 1692 and again in 1711. A new site was found in 1753, and extensions followed in 1859, 1874, 1884, 1894, and 1897. Remodelling has steadily continued from 1928 until the present comprehensive scheme, of which part still awaits completion. The Madras Medical College was established in 1835, and its clinical instruction from the first has been carried on in the General Hospital. The first x-ray outfit was installed about 1900, and twenty years later the Government organized a radiological service, temporary buildings in the hospital being at first utilized for this purpose. These soon became inadequate; in 1933 they had to cope with 75,780 sessions. The newly completed institute will be one of the largest and most up-to-date in the world. Instruction in radiology is to be one of its most important functions, and it is contemplated that the University of Madras will grant a diploma in this subject in the near future. It is hoped that much of the administrative expense will be met by contributions from paying patients. The building consists of two blocks, and includes diagnostic and treatment departments, a large remedial exercise and massage hall, a bed-sitting room for barium meal patients, and departments for clinical photography and electrocardiology. A feature is the incorporation of barium sulphate in the actual building bricks used in all the x-ray and radium departments; it is calculated that this affords protection equivalent to at least 8 mm. of sheet lead, while being much cheaper. The radium safe and the alcove in which it stands will be given a protection equivalent to twelve inches of lead. All the rooms in which the work will take place have been air-conditioned, so as to ensure that the temperature shall be 10° lower than that outside and the humidity be maintained at 60 per cent., no matter what the outside weather conditions may be. The entire conditioning plant works automatically. Besides serving the needs of the General Hospital, the institute will be available for the other smaller hospitals in Madras, and for patients coming from any part of the Presidency. The surgical block gives accommodation for an additional 124 beds and four sets of operating theatres. Provision for the nursing staff is made on the top floor, and it will now be possible to train thirty more nurses. The pathological block contains laboratories and rooms for pathology, bacteriology, and biochemistry, and also a large examination hall and library. It is three

stories high, and is connected with the east wing of the old hospital by a new wing, in which are situated the offices of the superintendent and laboratories for the professors. It is estimated that the cost of the whole hospital extension scheme will ultimately exceed fifty-two lakhs of rupees.

Scotland

Problems of Mental Disorder

In the report of the Glasgow Royal Mental Hospital for 1933 reference is made to the renovations and conversions of old buildings which have been effected. An admission centre for new female patients has come into being, the new ward consisting of eight bedrooms and a four-bed dormitory, with sitting room and dining room accommodation. The laboratory of the Neuro-Psychiatric Institute, which is situated in the grounds of the hospital, was opened a year ago, and is both well equipped and modern. An exceptionally large number of new patients were admitted during 1933, most of whom were acutely ill; nearly 60 per cent. were voluntary patients. The physician-superintendent, Dr. A. MacNiven, remarks that this fact is a forcible reminder of the high prevalence of mental illness in the community, and is an indication of the great need for active, preventive, and therapeutic measures. He sees little immediate hope of reducing this incidence, owing to the complexity of the causative factors. So far no one has had the temerity to outline a system of education and training which would have effective prophylactic value, even though great advances in knowledge have been made by psychological experts. It seems unlikely, therefore, that changes brought about by continued social progress, and resulting in an increase of material comfort and a general mitigation of the rigors of life, will result in a corresponding improvement in the standard of mental health of the community, for the reaction of the individual person to a good as well as an evil environment still remains incalculable. Dr. MacNiven adds that it is still necessary to point out that a mental hospital is something more than a prison, so deep-rooted in the community outlook is the fear of and antipathy to mental illness. Financial assistance for mental hospitals is scanty, and there is great need in Glasgow of a psychiatric clinic, similar in character to those in America and Germany. Such a clinic would enable the number of patients in the care of the physician to be diminished, would free the staff from administrative responsibility, and would promote research, which would have great economical benefits as well as improve the prospects of successful therapy. Dr. MacNiven thinks that erroneous ideas about the role of heredity in the production of mental disease are responsible, to a large extent, for the stigma which still clings to this disease. He fears that the prominence given to heredity in the report of the Departmental Committee on Sterilization may increase public anxiety unjustifiably. While mental defect in itself is a permanent bar to social independence, is in some cases inherited, and may therefore be suitably dealt with by sterilization, this is far from being the case in many forms of mental disease, and a distinction should be made. In regard to the latter, knowledge of the relative importance of heredity and environment is still so imperfect that there are very few cases in which a psychiatrist would feel justified in recommending sterilization. The growing interest of the general practitioner in the psychological aspect of his patients is indicated by the increased number of patients referred, in the year under review, to the Western Infirmary Psychiatric Out-patient Clinic. The total was 689, and the figures have

steadily risen since the inception of the clinic in 1910. In view of the importance of early treatment this rise is encouraging, but Dr. MacNiven recognizes that the psychiatrist is too often regarded as the last and not the first resort in cases of psychoneurosis and the minor neuroses. He comments also on the value of this clinic in the training of medical students.

Training of Nurses

The Departmental Committee recently appointed by the Secretary of State for Scotland to inquire into the training and registration of nurses has now held its first meeting. The meeting, which was of a preliminary nature, had under consideration the terms of reference:

"To inquire into the training and system of registration of nurses in Scotland, and to recommend what amendments, if any, should be made in the Nurses Registration (Scotland) Act, 1919, or the rules made thereunder, and what other steps, if any, should be taken to improve the existing system of training and registration."

In view of the wide terms of the reference it will be necessary for the committee to review the whole problem of nursing training and registration. Its aim will be to evolve, if possible, a more logical system than the present one, which, although an improvement on the position before the passing of the Nurses Registration Act in 1919, still achieves little in the way of mobility and interchangeability for nurses who desire to attain proficiency in all branches of their profession. The committee will not meet again until after the holiday period—probably some time in October—but in the meantime it is open to receive memorandums on the subject of the inquiry from persons and bodies interested. All communications should be addressed to the secretary of the committee, Mr. W. T. Mercer, Department of Health for Scotland, 121A, Princes Street, Edinburgh.

Gogarburn Institution for Mental Defect

At the opening of two new wards at Gogarburn Certified Institution, Edinburgh, on July 7th, the chairman, Councillor Mrs. Morison Millar, pointed out that the estate of Gogarburn had been purchased in 1923 by the District Board of Control to provide accommodation for at least 500 patients suffering from mental defect. There were already 330 patients, and the new blocks would accommodate 110 more. Bailie Raithby, the senior magistrate, said that Gogarburn Institution was an important part of the health services of the town council of Edinburgh. Occupation was provided for female patients in laundry work, kitchen work, sewing, and house work, and for males in gardening, stoking, and transportation of food and stores. There was also a school conducted by three teachers for the mentally defective children, and troops of scouts and guides had been formed among the patients.

The National Baby Week Council (117, Piccadilly, W.1) has issued two new publications in connexion with its propaganda on nutrition. A four-page pamphlet entitled *The Diet of the Expectant Mother*, by Stuart J. Cowell, M.R.C.P., professor of dietetics, University of London, is specially planned for midwives, and the majority of local supervising authorities distributed copies to midwives during National Baby Week this year. *Thoughts on Food and Feeding* is a propaganda leaflet intended to help mothers and housewives to become interested in the whole problem by securing the best nutrition at the lowest expenditure. Local supervising authorities are proving very ready to support the teaching to midwives embodied in the pamphlet by the distribution of it to mothers and housewives in their area.

Reports of Societies

OXFORD OPHTHALMOLOGICAL CONGRESS

The twenty-fourth annual meeting of this congress was again held at Keble College, Oxford, on July 5th, 6th, and 7th. The foreign and overseas members present were: Professor Joseph Meller of Vienna, Dr. J. Edward Rivera of Peru, Professor Berg of Upsala, and Dr. T. Donald Gordon of Durban.

PROCEEDINGS

These began on July 5th with a short speech from the Master, Mr. CYRIL WALKER, who referred in moving terms to the death of the Immediate Past Master—Mr. BERNARD CRIDLAND—which occurred only five days before the congress assembled. The congress had been founded twenty-five years ago by the late Robert Walter Doyne, but there was no doubt that the continued success of the meetings had been in very large measure due to the late Mr. Bernard Cridland, who was secretary for fifteen years, and became Master in 1929. He proposed the following resolution:

"That this meeting of the Oxford Ophthalmological Congress desired to express to Mrs. Cridland and family its profound sympathy with them in their recent bereavement; and to place on record their sense of the irreparable loss the Congress had sustained in the death of the Immediate Past Master."

Immediately afterwards Sir FARQUHAR BUZZARD opened a symposium on "The Functional Diseases of the Eye." He described how the opinions of ophthalmic surgeons had changed on this subject during the last twenty-five years, and that now a much more scientific attitude was taken on the matter.

He was followed by Mr. WILLIAMSON-NOBLE, who dwelt on the need for liaison between ophthalmology and psychiatry, quoting cases and discussing their treatment. He suggested a possible explanation of functional amaurosis with inactive pupils. He then discussed in detail the general considerations of ophthalmic methods of diagnosis to eliminate functional from organic causes of asthenopia. The variability in threshold stimuli in the production of headache in different patients was fully discussed. He thought it was possible to over-emphasize the importance of the functional element in the production of asthenopia.

Dr. WILLIAM BROWN said that the psychological factors at work in causing or sustaining functional diseases of the eye were identical in general—namely, inadequate solution of mental conflicts, faulty adjustment to the conditions of life, and a general failure to make headway along the individual chosen path. The baulking of fundamental instincts, especially those of self-preservation and sex, was responsible for much functional eye disease; but mental stress and shock arising in conditions involving eye strain would be especially potent in this direction, as in the case of miners' nystagmus. The visual symptoms in some forms of hysteria are of special theoretical interest, in that they illustrate with particular clearness some of the psychological characteristics of the illness. The disturbances of vision in war neurosis were very instructive, since they portrayed the working of psychological factors in a clear and simple form. In civilian cases of slow and prolonged development the psychological motive could only be revealed by long and painstaking analysis. There were a great number of cases of organic eye trouble with functional overlap, where the disturbance of function was in excess of that to be expected from the organic defect, and was due to the mental reactions of the patient to his disability.

A very interesting discussion followed, which was carried on by Sir ARNOLD LAWSON, Dr. TRAQUAIR, Dr. SEXTY GOOD, Mr. P. H. ADAMS, Dr. GEARY, Mr. GRAY CLEGG, Mr. F. WALKER, Mr. AFFLECK GREEVES, Mr. ALABASTER, and Dr. RIVERA. Mr. AFFLECK GREEVES related a case of retinal glioma in the second eye treated by radium externally. The first eye was removed when the patient was fourteen months old, and at the operation an ophthal-

moscopic examination was made of the other eye, which was discovered to be gliomatous as well. It was treated externally with radium in a wax mould; and when the case was seen three years later there was no sign of recurrence.

In the afternoon Dr. H. W. BARBER, physician in charge of the skin department, Guy's Hospital, read an exhaustive paper on the aetiology and treatment of some conditions affecting the eyelids. Eczema was first discussed at length as regards aetiology and treatment, then relapsing streptococcal lymphangitis with or without subsequent elephantiasis. Next Dr. Barber fully described the seborrhoeic state associated with blepharitis, styes, granuloma pyogenicum, sycosis, and rosacea. This was followed by a detailed description of miliary, lupoid, and rosaceous tuberculide, herpes simplex, and disturbances of the autonomic nervous system, and finally certain tumours of the lids were dealt with.

Mr. TUDOR THOMAS showed a patient who had had corneal graft performed on both eyes successfully, and he described the operative technique of the procedure.

Tea was taken at Oriel College, where the members were received by Dr. and Mrs. Franklin.

The annual dinner was held in Keble Hall in the evening, presided over by the Master, Mr. Cyril Walker. During the dinner the opportunity was taken of making a presentation to Professor ARTHUR THOMSON, who had just retired from the professorship of human anatomy in the University of Oxford, and who had kindly allowed the congress to hold its meetings in his department for the last twenty-four years.

OTHER PAPERS

On the morning of July 6th Dr. THOMSON HENDERSON read a very interesting paper on the constitutional factor in myopia. He brought forward the view that axial myopia was the result of constitutional factors, which, by inducing an inadequacy of the sclerotic, cause the posterior pole of the globe to give way under the normal intra-ocular pressure. Current theories as to the causation of myopia were criticized. It was shown that after the age of 5 years growth took place behind the equator, and hypermetropia resulted from an arrest of such development while myopia resulted from an over-extension. Congenital causes and hereditary influences were not considered to play a great part in determining myopia.

Mr. ARNOLD SORSBY read a paper on the pre-myopic state. The physical and biological conception of the normal eye was considered, and reference was made to the work of Steiger. The curves of the globe and the normal refraction in infancy were fully discussed.

The Doyne Memorial Lecture was given by Professor JOSEPH MELLER of Vienna, and was entitled "Tuberculosis and its Relation to Spontaneous Post-traumatic and Sympathetic Ophthalmia." The aetiological classification of the uveitides was criticized, and the opinion was expressed that a large proportion of these cases were of tuberculous origin. Professor Meller dwelt on the insignificance of the general tuberculous changes found in the lungs or glands of these patients. It was emphasized that only a positive focal reaction to tuberculin made the diagnosis certain. Sympathetic ophthalmia was next considered, and, after a short historical survey, reasons were given indicating its endogenous character. The results of Lowenstein's method of blood examination in cases of sympathetic ophthalmia were described. A culture from the tissue of the exciting eye in a case of sympathetic ophthalmia in 1932 showed tubercle bacilli. Further cases were also reported. In post-traumatic iridocyclitis bacillaemia was proved in 20 per cent. of the cases, but positive bacillary tissue findings were still lacking.

Dr. OLIVER PRATT read a paper on "The Influence of Diet in Ophthalmic Practice." Migraine was first discussed as regards its causation and treatment. Faulty fat metabolism was considered to be an underlying cause in many cases, and it was pointed out that assistance might be obtained for this defect by prescribing glucose. The inflammatory conditions of the cornea and conjunctiva were often associated with excessive carbohydrate consumption, and aggravated by lack of vitamins. Diabetes

was next discussed, and it was pointed out that when this was untreated myopia tended to develop. In diabetic retinitis diet alone was insufficient to arrest deterioration, and properly controlled treatment by insulin was essential.

Mr. BERNARD CHAVASSE read a paper on "Thermoplasty of the Extraocular Muscles." He described a method of heat coagulation of the motor nerve fibres destined to supply that portion of a muscle whose action it was desired to abrogate. A method was also described in which by the same means the effect of a muscle upon the position of the eye might be increased by longitudinal heat shrivelling of its tendon.

Mr. J. JAMESON EVANS and Mr. PHILIP JAMESON EVANS read a paper on "Some Remarks on the Aetiology and Treatment of Congestive Glaucoma." The aetiology of this condition was described as essentially one of angioneurotic oedema or thrombophlebitic oedema of the ocular structures. The necessity of preliminary treatment, which was mainly medical, was dwelt upon, and the actions and uses of acetylcholine were described.

On the morning of July 7th Mr. FREDERICK RIDLEY read a paper on "The Clinical Significance of the Composition of the Tears," with special reference to the action of lysozyme. Mr. SAVIN read a paper and fully described a case of uveoparotid fever. The patient improved after drainage of an empyema of the right maxillary antrum, and no evidence of tuberculosis was found. The last paper was by Mrs. LYTGOE, giving the result of some research work on the "Production of Rosettes in the Mammalian Retina." This paper was of great scientific interest, and was obviously due to much thoughtful and original work. A kitten was shown, in which rosettes had been developed in the retina, which could easily be seen with an ophthalmoscope.

The proceedings were closed by a short speech from the MASTER, who stated that 116 members had attended the congress.

OCCUPATIONAL THERAPY

A conference on occupational therapy, organized by the National Council for Mental Hygiene, was held at the house of the Royal Society of Tropical Medicine and Hygiene on July 11th.

Sir HENRY GAUVAIN, who was in the chair in the afternoon, defined occupational therapy as "occupation carried out under direct medical control and supervision with a definite therapeutic object." It should be prescribed, he said, in the same way as medicines with regard to the requirements of the individual patient. The movement was of recent development, and in this country we were merely on the fringe of the subject. The value, both psychological and physical, of the occupational treatment of all persons whose infirmities necessitated a prolonged sojourn in hospital or institutional environment was daily becoming more apparent to all those concerned in their care and restoration to normal health.

Dr. J. B. McDougall, medical director of the British Legion Village, Preston Hall, gave an enthusiastic and inspiring account of the trades and industries carried on there. The effect on the morale and general health of the men he described as amazing.

Dr. VERONICA DAWKINS, resident medical officer, Malmsbury Farm Sanatorium, Nayland, discussed the possibilities and limitations of occupational therapy in a sanatorium with a relatively shifting population. She laid great stress on the value of handicrafts, and described a regime carefully graded according to the patient's capacity for work and exercise. In addition to handicrafts, patients assisted in the utility services of the sanatorium, but in all cases this was carefully individualized and carried out under constant medical direction.

Dr. H. J. SAMPSON, resident surgeon, Royal National Orthopaedic Hospital, Brockley Hill, Stanmore, warmly espoused the cause in respect of patients treated in that hospital. He stressed its importance in re-educating crippled limbs as well as its psychological effect on the morale of the patients. Controlled occupation was one of the greatest advances in therapy of modern times.

OCCUPATIONAL THERAPY FOR MENTAL AND NERVOUS CASES

At the evening session Dr. NATHAN RAW, the Lord Chancellor's Visitor in Lunacy, was in the chair, and the discussion centred round occupational therapy in the treatment of patients suffering from mental and functional nervous disorders. The principal speaker was Mrs. ELEANOR SLAGLE, secretary and founder of the American Occupational Therapy Association. Her organization has official recognition, and supplies trained workers to all the principal Government institutions for mental illness and mental defect in the State of New York. She also supplies workers to mental hospitals and defective colonies in numerous other States. Mrs. Slagle described recent methods and advances in America. She emphasized the importance of using workers properly trained according to a recognized syllabus. The course in her school took two years, and included not only training in handicrafts but practical experience in their application to the treatment of patients in mental hospitals. It was also necessary, she said, that a considerable proportion of the nurses should have a knowledge of occupational therapy, so that they could supplement and assist the work of the specialist by helping the patients in the wards. It was the practice in America for nurses to have a short course of special training in the application of occupation therapy. She was convinced that this individualistic treatment, which brought the patients into contact with reality and obliged them to live a life approximating, as far as they were capable of it, to the normal was the greatest and most valuable weapon in the armamentarium of mental treatment.

Dr. J. R. REES, medical director of the Institute of Medical Psychology, warmly endorsed Mrs. Slagle's remarks, and said how greatly he had been impressed by the conditions in those mental hospitals in America where he had seen occupational therapy fully organized. It was proposed to start a school of occupational therapy in connexion with the Institute of Medical Psychology in London.

Dr. ELIZABETH CASSON, medical director, Dorset House School of Occupational Therapy, Clifton, Bristol, described the regime at her school. She was convinced of the immense therapeutic value of the time-table of exercise, occupation, amusement, and rest in the treatment both of the psychoses and of the psychoneuroses. Nothing was worse for patients than to drift about aimlessly. The carrying out of such a regime required the loyal co-operation of every member of the staff—medical, nursing, and occupation specialists.

Dr. NORAH HOWARTH, assistant medical officer at Severalls Mental Hospital, Colchester, described the forms of occupation therapy used in that hospital. She distinguished between the employment of handicrafts in the wards and in a special occupation centre, and occupation in the utility services of the hospital. The latter undoubtedly had a useful place in treatment provided that the occupation was fitted to the patient and not vice versa. For example, it was quite a different matter whether a patient was drafted into the laundry because she showed a special inclination for some branch of laundry work, or whether she was sent there because there happened to be a shortage of laundry hands.

Miss RUTH DARWIN, a Senior Commissioner of the Board of Control, said that she was convinced of the great value of occupational therapy in the treatment of mental illness. In order that it should be successful it was necessary to have co-operation from four angles: (1) the medical superintendent and assistant officers, who set the tone for the whole hospital, (2) the visiting committees, (3) the nursing staff, (4) the occupation teachers. Medical superintendents were coming more and more to realize its value, and in several hospitals this system was already in operation. Miss Darwin hoped that in the near future many more would come to appreciate it as a valuable and, indeed, necessary method of treatment. She was convinced that it would soon become a *sine qua non* of a well-conducted modern hospital. She quite appreciated in regard to hospital committees that they

must be satisfied that any expenditure incurred was justified by the results. She was sure that if visiting committees would acquaint themselves with the improved conditions in those hospitals where occupational therapy was well established they could not fail to appreciate its value. The nursing staff also of necessity took their tone from the medical officers. Where this was favourably disposed nurses had already shown themselves able and willing to co-operate to an invaluable degree with the trained occupationists. Occupation to be really successful must not be confined to a special room or an hour two or three times a week, but carried on daily in the wards. It appeared to be a psychological necessity for all humanity, whether mentally sick or mentally sound, to have some occupation with an object.

SUB-SPECIES OF ANOPHELES MACULIPENNIS

At a meeting of the Royal Society of Tropical Medicine and Hygiene at Manson House, on June 21st, Dr. L. W. HACKETT, assistant director, International Health Division of the Rockefeller Foundation, read a paper on the present status of our knowledge of the sub-species of *Anopheles maculipennis*.

Dr. Hackett said that the six varieties of *A. maculipennis*, as identified by their eggs, were each to be found in a number of different areas which were widely separated geographically. Within its own climatic range the presence of a given sub-species was determined by the orohydrographical conditions of the area, or, more particularly, the character of the surface water which the insect required for oviposition. No observations as yet suggested that an environment or micro-environment suited to the adult of either sex could determine the presence or prevalence of any sub-species. It had not been shown that individuals laying the same kind of egg varied significantly in physiology or behaviour, even if they came from different regions. Surveys of new zones proceeded, therefore, on the assumption that the egg type would serve to identify the sub-species, which was broadly homogeneous throughout its range in spite of adaptations to local conditions. Such modifications were apt to be quantitative (as in duration of sexual repose in winter, or range of micro-climatic tolerance) rather than qualitative and genotypic. The biological differences between sub-species were such as apparently to preclude hybridization in nature, and while cross-mating had occurred in the laboratory successive hybrid generations had never been obtained. The sub-species differed also in the frequency and regularity with which they bit man under present conditions of rural life, and since this determined the amount of malaria transmission some races were more consistent vectors than others. Thus *maculipennis (typicus)* and *melanoon* had little contact with man; *labranchiae* and *elutus* were continually penetrating into houses in relatively large numbers wherever these races occurred; while *messeeae* and *atroparvus* were easily deviated by domestic animals but overflowed into human habitations in search of food in various circumstances, among which were a disproportionate density of anophelines, a scarcity of animals, or the stimulus of certain physical states such as temperature, humidity, etc. Under identical conditions the various sub-species behaved quite differently, being drawn by diverse instincts into different environments and to different hosts. This in general explained their separate roles in the spread of malaria, but whether a given sub-species became a vector or not in a given locality depended also on a complex of local conditions, which might in one place lead it into continual contact with man or in another restrict it to animals to such a degree as to render malaria transmission highly improbable. The range of adaption of *labranchiae* and *elutus* was so wide, however, that there was no region in which either was known to be effectively deviated by domestic animals.

DISCUSSION

Professor P. A. BUXTON said that it was abundantly clear from Dr. Hackett's paper that races or sub-species of anopheles did exist, and that they were different in

anatomical characters, in details regarding breeding, and in their relation to malaria. Much of the published work on this subject was, however, in a very confused state. It could be classified in three very distinct categories: first, taxonomy; secondly, biometric facts; thirdly, physiological characters. Considerable progress might come about if attention were paid to physiological characters, not only in the field but also in the laboratory. If, for instance, a stock of *atroparvus* were taken and bred at different temperatures, or fed differently, would one get differences in the eggs or the larvae or the adult structures? No one had any real knowledge of what the answer to that question would be.

Dr. F. W. EDWARDS of the British Museum agreed that the race of *maculipennis* showed very different characters, at least in the eggs, but in regard to certain other distinctions some were less easy to understand. The chief point of distinction in the males was whether a particular hair or spine on the tail end was blunt or pointed, and that might be a matter of mere label rather than pure fact. On the other hand, probably more attention might be paid to colour pattern. However, if observers themselves could not distinguish the insects, the latter managed to distinguish each other, for they never made a mistake on mating, as exemplified by certain species of gnats in this country distinguished only by their minute characters, such as a tiny wing spot and so on. How they did it was a mystery, but undoubtedly the whole truth was being approached as a result of the investigations of Dr. Hackett and others.

Colonel S. P. JAMES remarked that, not being an entomologist, he was a little bit confused, but felt quite sure that all would in time agree about some, if not all, of the varieties of *maculipennis* that Dr. Hackett had described. The late Mr. Richard Burton as early as 1916 had noted two forms of *maculipennis* in Shropshire, one of which was found hibernating completely in the winter in clock towers, church steeples, and the like, while the other passed the winter in stables and in the bedrooms of some kind of houses. Later, in association with Mr. Shute, a great number of observations were made on the habits of these two different forms of *maculipennis*, which were of value in explaining why malaria in England had such a peculiar distribution, especially along the coast, and why it was particularly a disease of certain houses. This house mosquito was now known to be *atroparvus*.

Sir RICKARD CHRISTOPHERS said that the discovery of these races of *maculipennis* was by far the biggest thing in the epidemiology of malaria in recent years, and it was a curious thing that this work should have originated in Western Europe with its three species of anopheles. Further, although in the Tropics it was known that the habits of anopheles were very important, it came somewhat as a shock to find that the presence of malaria in Holland, for example, turned upon a most trivial habit of a particular variety, which was scarcely distinguishable from others. But the greatest change this new work had made concerned the conception of what a carrier species was. Dr. Hackett, who had taken the foremost part of any worker in studying this question, put it clearly in one sentence: "A carrier species is so by reason of the relative frequency with which it bites man twice." Once is not enough—it must bite man twice! Dr. SENIOR-WHITE stated that four years ago Sir Rickard Christophers had said at Algiers that the study of *maculipennis* was becoming a separate science: he trembled to be in charge of an area in the Tropics containing twenty-one so-called species of anopheles, many of which, even on superficial examination, presented something queer in species. Major AUSTEN discussed the vexed question of nomenclature, and supported the plea put forward by Sir Rickard Christophers for its revision; he also upheld Professor Buxton's suggestion for more laboratory investigation. Sir MALCOLM WATSON said there was no doubt that the malaria reports of the League of Nations between 1924 and 1928 had discouraged the prevention of malaria throughout the world. They cast grave doubts on the relationship between anopheles and malaria, and certainly called a halt in many parts of the field. Dr. Hackett's work in Italy and Sardinia gave the malaria position a better course.

In reply, Dr. HACKETT dealt with the status of sub-species, and agreed it might be better to accept Fulleroni's recent suggestion by giving another name to *typicus*; then all the races would have names and none of them would be called the type. He agreed with Professor Buxton that physiological studies were important, and an enormous cage which contained pigs and a stable had been made in Albania, which Lewis was now filling with *typicus* to see whether they could mate under conditions as natural as possible.

STERILIZATION OF THE UNFIT

At a meeting of the London Association of the Medical Women's Federation, held at B.M.A. House on June 26th, with Professor MARY LUCAS KEENE in the chair, Dr. LETITIA FAIRFIELD spoke on eugenic sterilization of the unfit.

Dr. Fairfield based her observations on the recently issued report of the Departmental Committee on Sterilization. She pointed out that the wide popular interest in sterilization had grown out of two main factors. First, the increase in biological knowledge of the hereditary factor in mental and physical disease, and secondly, the sociological outlook, which attributed numerous evils of society to mental and physical "unfitness." The appointment of the committee was inevitable, for it had become fashionable to regard sterilization as a panacea, and in the case of mental deficiency, for example, the over-emphasis on sterilization had been allowed to swamp every other aspect of a many-sided problem. It was only fair to state that the efforts of many prominent eugenicists and the findings of the Departmental Committee's report were directed towards correcting these exaggerated claims. Dr. Fairfield then reviewed the findings of the report. She considered that the legal obstacles in the way of the eugenic sterilization of persons of normal mentality had been somewhat exaggerated. As a matter of fact, no one who was able to pay for such an operation at the present day had the least difficulty in getting it done, and probably more hospitals were performing such operations than was supposed. No case of a surgeon suffering any penalty for doing a eugenic sterilization was on record, and it was impossible to imagine such a case being brought into court, provided that genuine grounds existed for believing that diseased offspring might be procreated. It was, however, recognized that the sterilization of mental defectives was undoubtedly illegal.

In examining the present knowledge of the causation of mental defect the committee had evidently found itself on highly contentious ground. All their witnesses agreed on the important part played by "heredity," but they were not at one on the exact meaning of the term. Some would include in the family tree any deviation from the normal, including epilepsy, instability, delinquency, and insanity, while others would confine the term to the transmission of a single defect such as certifiable mental deficiency. Naturally the percentage of "hereditary" cases differed according to the view taken, the variation extending from 5 to 80 per cent. The report had recorded some interesting researches into the mentality of the offspring of defectives, who showed an unexpectedly high rate of mental deficiency—namely, nearly one-third of surviving children. Dr. Fairfield pointed out, however, that the figures were overweighted, as defective offspring were likely to call the attention of the authorities to defective parents. The report further blackened the picture by bracketing the "subnormal" and defective children, although the former might be little different from the general population. While assessing the part played by environment in causing mental abnormality, many witnesses stressed the point that this factor acts in combination with defects of heredity, the thesis being: "environmental factors may accentuate inherited weakness." The evidence also brought out a point which was still often overlooked—namely, that mental deficiency was so devious in its manifestations that it could not conceivably be a single unit transmissible on Mendelian lines, though certain sub-varieties might be. The final

recommendations of the committee condemned compulsory sterilization as unjustifiable in the present state of knowledge of genetics, and likely to arouse public hostility. It was not clear, however, whether it would be possible to keep voluntary sterilization really voluntary. It was difficult to imagine the precautions which would prevent enthusiastic committees from using the social services (such as outdoor relief) or the bait of discharge from an institution as an inducement to sterilization. This was avowedly happening in other countries where sterilization measures were on the Statute Book. As regards high-grade mental defectives, the committee evidently considered it an easy matter for a doctor to decide whether they were or were not mentally competent to give a valid consent to the operation, but no standards were laid down, and Dr. Fairfield considered that in practice the point would be a very difficult one to determine. As regards mentally normal persons, it seemed to have been overlooked that any attempt to regulate voluntary eugenic sterilization would seriously restrict the freedom of action now enjoyed by the "well-to-do"—that is, by all who could afford to pay for an operation. In future they would have to submit to an elaborate process, beginning with two medical certificates, and involving reference to the Ministry of Health, and possibly to the Board of Control, or a special advisory committee of experts. Notoriously, in the sight of a Ministry a thousand years was but as a day, and the loving couple who longed to be united could hardly be expected to await inevitable official delays. It seemed probable that the regulation of voluntary sterilization was doomed to failure. In view of the small proportion of institution cases which would be suitable for sterilization, and the grave risks involved by any form of legislation on the subject, it seemed doubtful whether the recommendations of the report would receive general support.

Dr. C. P. BLACKER, the general secretary of the Eugenics Society, said he found himself in entire agreement with most of the points which Dr. Fairfield had made. The propaganda in favour of legalizing eugenic sterilization would, he said, do more harm than good if it were seized upon by local authorities as a justification for inertia, or if it were interpreted by the general public as a measure likely to save the pocket of the ratepayers. Much confusion also centred around the meaning of the word "heredity." According to the report of the Committee on Mental Deficiency appointed by the British Medical Association, the term "heredity" implied "that in the ancestry of any given case of mental deficiency there has existed a morbid condition of bodily and/or mental development, which may have taken the form either of mental deficiency or of some neuropathic condition, or of some other defect due to damage inflicted to one or other of the germ cells before fertilization." According to this sweeping definition we would be justified in regarding as hereditary a given case of mental defectiveness if it were known that there had occurred in the ancestry of that defective a case of cleft palate in the time of William the Conqueror. Careful scrutiny of recent American and Continental investigations into the heredity of mental deficiency pointed to the conclusion that the more carefully the pedigree was investigated the greater was the importance attributed to heredity as a causal factor, and the larger was found to be the percentage of parents of high-grade defectives who were themselves on the borderline between subnormality and certifiable defectiveness. At the same time, it should be remembered that, though discussions on sterilization continued to focus themselves upon mental deficiency, the recommendations of the Brock report extended far beyond this sphere. The eugenic benefits, in fact, of legalizing the voluntary sterilization of mental defectives would probably turn out to be small, as compared with the results of legalizing it for persons who had recovered from mental disorder and for persons who exhibited or carried mental or physical disease or defect. The results, said Dr. Blacker, of the uncertainty in regard to the present state of the law relating to the sterilization of persons who are *compos mentis* had at present the effect of discriminating against the poor. The legal risk, admittedly small, was willingly taken by

surgeons who operated, in a private capacity, upon paying patients; the same surgeon, however, before operating upon a hospital patient usually found it necessary to obtain the consent of the superintendent of the hospital. This consent was often withheld, partly for fear of alienating Roman Catholic subscribers to the hospital, and partly because, in view of the already long waiting list, many hospitals hesitated to incur the smallest legal risk. Such discrimination between rich and poor was unfair, and it constituted a good argument for regularizing the position for people of all classes by Act of Parliament. In the matter of safeguards, said Dr. Blacker, a course had to be steered between two opposing camps of critics, and, in his opinion, the recommendations of the Brock Committee constituted a happy *via media*. Some safeguards, he thought, were necessary. It was to be remembered that vasectomy was a simple operation, capable of being performed under a local anaesthetic; it took but a few minutes, and necessitated at most a day's absence from work, yet it produced irreparable and irreversible effects. Every new law was exposed to certain criticisms and objections. Dr. Blacker was far from denying that a voluntary sterilization law along the lines of the recommendations of the Brock Committee was exempt from these, but in deciding whether to oppose or to support it the question we had to ask ourselves was: "On balance did the advantages outweigh the disadvantages?" and he believed that in this instance the answer was "Yes."

CORRESPONDENCE

Prescription of Thyroid

SIR,—Your article in the *Journal* of June 9th serves a very useful purpose in drawing attention to the danger of prescribing overdoses of thyroid owing to the confusion between the dosage of fresh gland and dry gland preparations to which you refer. The letters of Dr. W. Martin and of Mr. N. Evers in the *Journal* of June 23rd show there is still some difference of opinion as to the relative strength of the two, but in practice I have found that, as you state, 1 grain of dry thyroid B.P. is equivalent to 5 grains of fresh gland. The dangers and ill effects of continued overdosage are well illustrated by the cases of thyroid addiction described by Dr. S. W. Patterson in the *Journal* of July 7th.

In prescribing dry thyroid it is important to bear in mind the amount of it which is equivalent to the daily output of the normal gland of an average adult. This varies in different individuals, but long experience has shown that in the majority of fully developed cases of myxoedema, in which the gland has become functionless, a daily dose of from 1 to 2 grains is sufficient to restore and maintain good health for many years, so that this amount may be taken to represent the daily quantity of secretion produced by a normal gland. In the treatment of these cases there is nothing to be gained by exceeding these doses. In mild cases of hypothyroidism, in which the gland still supplies a small but insufficient amount of secretion, a single daily dose of 1/2 grain is adequate. When it is desired, as a means of treatment, to raise the basal metabolic rate above the normal level larger doses are necessary, but should be employed under medical supervision, so that the effect on pulse rate and weight and, if possible, on the basal metabolic rate may be observed, and the dose diminished as soon as any ill effects appear. The official B.P. dose is given as 1/2 to 5 grains. The latter is too large, as the continued use of 5-grain doses two or three times a day is apt to produce the symptoms of induced hyperthyroidism observed in Dr. Patterson's cases.—I am, etc.,

Manchester, July 11th.

GEORGE R. MURRAY.

Pyloric Stenosis

SIR,—The interesting article by Dr. H. L. Wallace and Mr. L. B. Wévell and recent correspondence in the *Journal* on congenital hypertrophic stenosis of the pylorus, reveal many points of view on which differences are manifest and results by no means uniform. As one of your correspondents states, team work is essential; the practitioner, the paediatrician, and the surgeon all play their parts, but sufficient stress is not laid by him on the importance of early diagnosis and the part played by the practitioner in making this possible. Valuable as is the assistance of the paediatrician in pre- and post-operative care, the surgeon prefers the infant to reach his hands within, say, ten days of the onset of cardinal symptoms, before wasting has become excessive.

Under such circumstances the mortality should not be more than 5 per cent. As I pointed out in 1927,¹ a group of ninety cases operated on at the Birmingham Children's Hospital had a mortality of 40 per cent. Among these were fifteen "private" patients, none of whom died. These cases were treated in the private ward of the hospital under conditions exactly comparable to those in the general wards, but they differed inasmuch as symptoms had, on the average, only been present for thirteen days in this group, compared with eighteen days in the cured cases from the ordinary wards, and twenty-five days for those who died following operation.

If a palpable tumour is to be a cardinal point in the diagnosis, as we are accustomed to regard it, the examination must be painstaking and prolonged. Its presence clinches the diagnosis, and differentiates cases of pyloric spasm. In the last two years, in cases referred to me by my colleague Professor Parsons, palpable tumour was found by him in forty-one cases out of forty-three. In one case it was definitely not felt, and in the other no note was made.

Radiography appears to be used but little in this country as a routine method of differential diagnosis. In France it appears to be otherwise; Poucel, in his recent monograph,² regards it as a normal and harmless procedure. In Birmingham we regard it as usually unnecessary and not altogether harmless.

Since the commencement of 1930 I have operated on eighty-nine cases to date, with seventeen deaths—a mortality of 19 per cent. This compares favourably with the group of ninety cases which I published in 1927 with a mortality of 40 per cent.; and, though it is undoubtedly true that most of the seventeen cases might have been saved with earlier diagnosis, yet I think great credit is due to those upon whom the responsibility for the initial diagnosis rests—namely, the practitioners—for the improvement in results already manifest in a disease which has only been generally recognized and adequately treated for just over a decade.—I am, etc.,

Birmingham, July 10th.

SEYMOUR BARLING.

Preliminary Ligature in Toxic Goitre

SIR,—There are a number of cases of toxic goitre in which a primary radical operation, even in the best hands and after careful preliminary treatment, is associated with a considerable, indeed an unjustifiable, risk. I refer particularly to cases in which the goitre is large and the patient over 40 years of age. A preliminary ligature of both superior thyroid arteries will almost invariably effect a notable improvement in such cases. I would go further and maintain that the subsequent thyroidectomy should be done in two stages.

¹ *Lancet*, September 3rd, 1927, p. 492.

² Poucel: *La Sténose Hypertrophique du Pylore chez le Nourisson*. Paris: Masson et Cie. 1934.

A death following thyroidectomy means bad management—a failure to assess just how much the patient will stand at one time. I look back to some of my early cases in which death followed a subtotal thyroidectomy with keen regret. I failed to discriminate and to recognize the case in which operation by stages is the secret of success.—I am, etc.,

Edinburgh, July 13th.

D. P. D. WILKIE.

Notification of Tuberculosis

SIR,—In the closing paragraph of "Musings in the Garden: Fifty Years' Association with the Tubercle Bacillus," published in the *Journal* of June 23rd, I expressed the hope that I had not trodden unwittingly on anyone's toes. Least of all could I dream of disturbing my old and honoured friend, Sir Arthur Newsholme, who takes me rather to task in an historical note in this week's issue for doing him less than justice. Nothing was further from my thoughts.

Looking back through the years, Sir Arthur may realize the feeling of acute disappointment which overtook me when, eighteen years after advancing a strong plea for the compulsory notification of pulmonary tuberculosis—a plea which was based on continuous observation at the tuberculosis dispensary (1887-90)—I read in his volume, published in 1908, that the considered opinion of the Chief Medical Officer of the Local Government Board of England was that, at that date, "it would be inexpedient, unwise, and of relatively little use to advise the general adoption of compulsory notification of phthisis."

This recalled the "stone wall" of which Sir Henry Littlejohn had warned me eighteen years previously. It was the more disappointing, since in the interval compulsory notification had been introduced in New York in 1897 through the weighty authority of Herman Biggs, and the Local Government Board of Scotland, in a circular dated March 10th, 1906, had declared that notification was necessary if the Public Health Act (Scotland) was to be applied effectively to pulmonary tuberculosis, with the result that by 1908 nine local authorities, including Edinburgh, had applied for the Board's sanction to the adoption by them of compulsory notification. The fact would seem to have been that Sir Arthur was himself up against a stone wall, and the words quoted represented less his personal views and rather those of the Chief Medical Officer, who was encountering, as he tells us, "almost insuperable difficulties in overcoming central official opposition."

I would assure Sir Arthur that, in citing his words in my address, I was recalling events of the past in the simplest way possible. There was no *arrière pensée*. Happily, as we get up in life, we become more understanding of the complex conditions which govern the course of events.—I am, etc.,

University of Edinburgh, July 13th.

R. W. PHILIP.

Point of Entry of the Tubercle Bacillus

SIR,—Sir Robert Philip, in his most interesting address "Musings in the Garden" (*Journal*, June 23rd, p. 1105), has once again done a great service to the cause of combating tuberculosis by giving it as his opinion that the lymphatic system is the main port of entry of the tubercle bacillus. My own much more limited experience definitely confirms this conclusion, and in a paper published in the *Journal* in August, 1929, I endeavoured to show that pulmonary tuberculosis was secondary to lymphatic infection. The opinion that infection is mainly by the respiratory tract dies hard, although all the facts, as I see them, are entirely against such an assumption. I was interested in his view that the tubercle

bacillus can pass through a young mucous membrane without showing any trace of its passage, and that no gross lesion may be evident in the lymphatics. Certainly the percentage of children showing small, shotty cervical glands is very high, even in those enjoying excellent health. It is only very occasionally that infected glands call for surgical intervention. A good many years ago I asked myself the question, Is the lymphatic gland of the child more permeable than that of the adult? I passed on this question to a distinguished physiologist, but he was unable to give an opinion. On clinical grounds I certainly think that the young lymphatic glands are more permeable, and, if we can accept this assumption, it becomes much easier to accept the idea of the lymphatic system as the main port of entry, and follow intelligently its course.

In my own experience of children the number showing clinical evidence of tuberculous infection was as high as 15 per cent., and the percentage was highest among those suffering from some infection of the nasopharyngeal cavity. The percentage of children giving a positive reaction to tuberculin is, of course, very much higher. The natural drift of any infection, particularly a chronic and persistent invader like the tubercle bacillus, is towards the lungs, and if the resistant power of the lungs was not very high the percentage of sufferers from pulmonary tuberculosis would be very much greater. We know that the tracheo-bronchial glands are very frequently tuberculous, and in that respect the main principle of Parrot's law is correct in stating that the infection present in the bronchial glands is secondary to infection from the lungs. It does not necessarily follow, however, that there was any real invasion of the lung parenchyma. It is much more in keeping with our knowledge of the history of pulmonary tuberculosis cases that the tubercle bacilli, coming along in small numbers, are quickly taken in hand by the defensive mechanism and hurried towards the root glands. The continual bombardment, so to speak, must lead to pathological changes in those glands which would render them less permeable, and the tubercle bacilli would be held up in that situation.

This suggested course of events would explain the high percentage of children giving a positive tuberculous reaction compared with the really small percentage showing definite evidence of pulmonary tuberculosis. When adolescence is reached the tuberculous infection has been established for many years, and the subsequent course depends on the efficiency of the defensive mechanism, as well as the degree of infection, which again is influenced by many factors—such as hygienic conditions, worry of any kind, depression from long and serious illnesses, etc. There are no reliable means which will enable us to make an accurate assessment of subsequent events.

Acceptance of this theory makes it easier to follow the course of the disease. Fibroid phthisis can be explained by a slow, backward spread of the infection along the lymphatics; even bronchiectasis could be similarly explained. A sudden invasion of a lung, or part of a lung, repeatedly noted by me, would result from an infected caseous gland rupturing into a bronchus; miliary tuberculosis would be due to a sudden mass infection from an acutely inflamed tuberculous gland finding access to the lungs, via the blood stream, and this would also explain the widespread infection. Miliary tuberculosis and tuberculous meningitis often attack people who have previously enjoyed good health, particularly so in the case of meningitis. A sudden mass infection from outside the body of a relatively healthy person, via the respiratory passages, is much less likely than a mass infection from an already infected source inside the body.

All my experience and observations, extending over a period of twenty years, forced me to the above con-

clusions; infection from some unknown origin, coming like "a bolt from the blue," is not in the least convincing.—I am, etc.,

Birkenhead, June 29th.

D. J. GAIR JOHNSTON.

Sunbathing and Tuberculosis

SIR,—I do not wish to deny the possibility that prolonged exposure to sunlight may aggravate active pulmonary tuberculosis, or even be responsible for the lighting up of a latent focus—a popular belief anyway. Nevertheless, before the cases described by Drs. Hope Gosse and Erwin (July 7th, p. 15) are accepted as evidence in support of this hypothesis certain points should be kept in mind. Only five of the eleven patients had been in good health before the sunbathing. In the remainder symptoms had been present before, which suggest that the aggravation afterwards might well have been due to the natural progress of the disease. In view of the universal popularity of sunbathing during the last two or three years the five cases could presumably be the result of coincidence. Moreover, it is possible that some other associated factor may play a part—for example, the excessive exercise whilst in an unfit condition often indulged in during a holiday. Finally, it would have been of interest to compare the proportion of fair- and dark-haired individuals in the exposed and non-exposed patients in view of the difference in tolerance to sunlight by pigmented and non-pigmented people.

Drs. Hope Gosse and Erwin's paper has attracted attention to a subject which urgently requires further investigation, owing not only to the popularity of sunbathing, but to the difference of opinion which, I believe, still exists on the danger of ultra-violet therapy in pulmonary tuberculosis.—I am, etc.,

Cannes, July 12th.

G. GREGORY KAYNE.

SIR,—There is little doubt that the danger referred to by Drs. Hope Gosse and Erwin does exist when exposures are uncontrolled and over-exposure occurs. The warning is indeed timely. But their complete condemnation of heliotherapy as a therapeutic measure in pulmonary tuberculosis is not confirmed by the practical experience of some twelve years in this institution, where heliotherapy has been used for non-febrile pulmonary cases throughout this period. For the last six years no less than 43 per cent. of all cases of pulmonary disease have had a course of heliotherapy, and 40 per cent. have had general carbon arc treatment in the winter months. The type of case admitted during these years may be briefly indicated by the fact that 58 per cent. were classified as B3 cases. The treatment must, however, be properly organized under experienced medical supervision, and a nurse should be on duty solely for the purpose of accurate timing of exposures, checking pulses and temperatures before and after exposures, and so on, without other duties to interrupt her. Under these conditions I have never seen any serious ill effects, for unsuitable cases are quickly detected and treatment is limited to shade exposures only or given up.

Nearly all our most successful cases have had light treatment in some form in addition to any other special treatment which may have been given. A moderate dose of heliotherapy increases metabolism whilst the patient is still at rest, and is theoretically just what these patients require. In practice, however, there are many patients who have not the power of response to this stimulus, just as there are similar cases of non-pulmonary type whose response is inadequate. Weakly or toxæmic patients are generally unsuitable, as are those with a history of frequent hæmoptysis or staining. Neverthe-

less, the figures given above show that many cases are suitable, and in my opinion this method of improving general fitness ought not to be neglected.

A striking indication of the value of heliotherapy and aerotherapy is the improvement in the condition of the skin, subcutaneous tissue, and muscles—a change so marked when dealing with non-pulmonary tuberculosis, and obtainable also in many pulmonary cases. This change is generally accompanied by an increased feeling of well-being and improved appetite and sleep. I agree entirely with the authors, however, that the treatment is dangerous without proper control. Another danger is that of patients sitting in the hot sunshine when fully clothed for an unlimited time without supervision. This is a common cause of fever in pulmonary patients, and one not generally realized.—I am, etc.,

J. E. WOOD,

Medical Superintendent, King George's
Sanatorium for Sailors.
Liphook, Hants, July 13th.

Ligature of the Innominate Artery

SIR,—Sir William Wheeler's reference in the *Journal* of July 7th (p. 38) to the late Mr. Coppinger's celebrated case of ligature of the innominate artery prompts me to state that a second successful ligation of the innominate artery was carried out by myself, in the same hospital, in 1932. The patient, a middle-aged woman, was admitted with a rapidly growing and intensely painful right subclavian aneurysm. The Wassermann reaction was negative. A curious feature of the case was that no pulse could be felt in the left subclavian or in any part of the left arm. The artery, exposed by removal of the inner end of the clavicle and right half of the manubrium sterni, was doubly ligated with stout linen thread. The common carotid was not tied. The patient made an excellent recovery, pain completely disappeared, the aneurysm consolidated, and she is now carrying on her occupation of insurance collector as actively as ever.—I am, etc.,

Dublin, July 9th.

CHARLES MACAULEY.

Tests of Renal Function

SIR,—Dr. F. S. Fowweather's paper on "The Examination of Renal Function" (*British Medical Journal*, July 14th) is valuable in pointing out the fallacies of the urea clearance test as ordinarily performed, and also in suggesting methods by which these fallacies may be minimized. The chief objection to the test, in my opinion, is its obvious pretence to a scientific accuracy which it does not possess, even in its modified form. In Table II of the paper referred to, showing the results of the test in patients with renal disease, the only case mentioned as having uraemia shows a urea clearance considerably better than the average for the group. Actually I do not find in practice that the urea clearance test is as helpful as a *dilution and concentration* test (a more accurate way of performing the simple test of function described by Dr. Fowweather), and examination of the blood for non-protein nitrogen and indican. The urine tests show what the kidney can do, and the blood tests show what it has been doing—that is, how near the patient is to uraemia.

There are two statements in Dr. Fowweather's paper which I would like to question. The first is that in chronic nephritis "albuminuria is rarely more than slight, and often is absent altogether." This is an assertion which I hold to be erroneous, handed down from the days when high blood pressure was sufficient evidence for a diagnosis of "chronic interstitial nephritis"—that rubbish heap of cardio-renal disease now fortunately unnecessary. In all cases of true chronic nephritis albuminuria is

definite, if not copious (usually 2 to 5 grams per litre), and in cases of hypertension with nephrosclerosis all those that I have seen develop renal failure have had a very definite and constant albuminuria. In fact, I regard the presence of albuminuria (more than a trace) as a fairly good rough indication of involvement of the kidney (nephrosclerosis) in essential hypertension. The only exceptions have been cases of essential hypertension which were without serious renal insufficiency until heart failure occurred, and, by lowering the blood pressure, caused oliguria and consequent uraemia.

When oliguria develops in such a case the specific gravity of the urine rises; and this brings me to the second statement, which is that "failure of concentration is compensated for by polyuria." Surely the truth is that "compensatory polyuria causes failure of concentration." The polyuria represents the functional reserve¹ of the kidney, called out on account of the loss of renal substance. According to Verney's law the composition of the urine depends upon its rate of secretion. The rapid secretion causes the failure of concentration, as is well shown by the above observation that if anything (such as heart failure) interferes with the rate of secretion the concentration of the urine increases. Thus the power to produce a moderately concentrated urine is not lost, but merely in abeyance.—I am, etc.,

Sheffield, July 16th.

ROBERT PLATT, M.D., M.R.C.P.

Agranulocytic Angina

SIR,—I have read Dr. A. Daly Briscoe's account of his very interesting case in the *Journal* of July 14th (p. 61). The dysuria and the pain on defaecation which "became the prominent features of the case," and were associated with a large tender prostate, suggest that the condition may have been secondary to some focus of acute infection in the prostate, and the case, therefore, one of malignant neutropenia rather than a primary agranulocytosis.

Dr. Briscoe rightly stresses the rarity of the disease, but I cannot accept his statement that only five cases have been reported in this country when he omits to mention the case I myself recorded in 1933²—this was the first case in English medical literature in which pentose nucleotide K 96 was used. Even though the reported cases are few the true incidence of the disease is not thereby reflected: a record of a case is only made if it presents unusual features, if a new therapeutic agent is made available, or if light can be thrown on the cause.

Out of a most extensive literature on the condition two facts only of importance have emerged—the value of pentose nucleotide in treatment, and the importance of amidopyrine, either by itself or in combination with a barbiturate, in causation; I feel that no writer should record a case without mentioning whether these drugs have been given or not.

There seems no question, from reports from all parts of the world, that amidopyrine plays a part in the production of agranulocytosis; to quote from the latest report of the Council on Pharmacy and Chemistry of the American Medical Association³: "In fact no other agent has been found, either chemical or bacterial, which has been a factor in causing so many attacks"; "No definite case has been recorded in which a barbiturate alone is responsible," but in many cases a combination of amidopyrine and a barbiturate has been incriminated.

Individual susceptibility to amidopyrine is doubtless a factor, but caution in its use is indicated, with control of the white blood cells if its use is continued. The difficulties of the position are increased when the presence of

amidopyrine (pyramidon) is concealed by the name of some proprietary preparation of it with a barbiturate—alional and cibalgin are two examples of this. I should add that in the case I published the patient had not taken amidopyrine or a barbiturate.—I am, etc.,

ERNEST BULMER, M.D.,

Birmingham, July 15th.

M.R.C.P.Ed. and Licd.

Asthma and Chronic Bronchitis

SIR,—Dr. H. S. Russell in the *Journal* of June 16th (p. 1097) writes: "It appears probable that the action of sodium iodide [in cases of asthma and chronic bronchitis] depends mainly on stimulation of thyroid activity, and that equally good results might be obtained by the administration of tab. thyroid. B.P."

There is no conclusive evidence that cases of asthma (and chronic bronchitis) are in particular the result of thyroid insufficiency. Both chronic bronchitis and asthma essentially are due to disorder of the vago-sympathetic respiratory complex, an anatomical fact which may be amply demonstrated by careful x-ray investigation of the bronchial tree injected with a radio-opaque substance. Lipiodol injections indicate also that asthma, asthmatic bronchitis, chronic bronchitis, with their satellites bronchiectasis and emphysema, are each and all due to the effects of this disorder in the respiratory department of the autonomic nervous system. The basal cause, or starting-point, of the incoordination of the normal balance between vagal and sympathetic influences is another matter, which must needs be referred to biochemists and to the physiological laboratory. It is fundamentally a question of nutrition.

Adrenaline antagonizes vagal influences by stimulating the sympathetic. The suprarenal glands supply adrenaline, the secretion of which is under the control of the autonomic nervous system. It is logical, tempting, but perhaps speculative to suppose that there is an internal secretion which antagonizes sympathetic influences in the bronchial tubes, or which stimulates the vagus nerve as in a parallel fashion adrenaline antagonizes the bronchial vagus, the vagal secretion being also under the control of the autonomic nervous system, which, incidentally, supplies all the viscera. That this is not wholly speculative is indicated by the recent work of Dr. E. Arnold Carmichael and Professor F. R. Fraser on the effect of acetylcholine in man.¹ The autonomic nervous system is not dependent on the metabolism of a single endocrine gland. The relation of the autonomic nervous system to respiratory ailments needs further investigation, having in view the work on the involuntary nervous system by W. H. Gasrell and J. N. Langley, and its more recent application to diseases of the viscera under the control of the autonomic nervous system.

The stethoscope, introduced by Laennec in 1819, in conjunction with percussion, recommended by Auenbrugger in 1751, has been relied on for diagnosis in diseases of the chest for over a hundred years, and it is no disparagement of these still indispensable methods to say that for diseases where bronchial tubes are in question the stethoscope must make room for later developments in diagnostic procedure—x rays, lipiodol, the bronchoscope. The evidence of the eye is less open to error than that of the ear, since with the stethoscope auditory impulses must be transformed into mental pictures, not always true.

When Pasteur and his contemporaries established the part played by micro-organisms as causal factors in disease, bacteriology claimed chronic bronchitis as a bacteria-produced disease. It would appear from clinical and anatomical evidence derived from x-ray examination

¹ Verney, E. B.: "The Reserve Forces of the Kidney," *Lancet*, 1931, ii, 63.

² *Lancet*, May 27th, 1933, p. 1119.

³ *Trans. Amer. Med. Assoc.*, June 16th, 1934, p. 2183.

¹ *Heart*, 1933, vii, No. 3-4.

of bronchial tubes injected with lipiodol that bacteria, though undoubtedly present in the bronchial tree, and indisputably modifying the cause of, and producing definite reaction in, the disorder, are not the primary cause of chronic bronchitis. There is evidence, supported by the same method of examination, that asthma, chronic bronchitis, bronchial asthma, bronchiectasis, and emphysema, usually considered independent diseases, need re-investigating, re-sorting, reclassifying, rearranging into a respiratory group whose fundamental causes must be looked for among disorders of the autonomic nervous system, which must be left by the anatomist to the biochemist and to the physiological laboratory. It may be that we shall have to await the successful application of cinema technique to the *x*-ray and radio-opaque-substance investigation for visual confirmation of this statement. (Some writers claim that they can make out movements in the lipiodolized bronchial tubes depending on vagal and sympathetic influences—by screening the lung after the injection.)

With regard to evidence which may be drawn from stained pathological sections of the bronchus in chronic bronchitis—with the exception of the micro-organisms in the expectoration and the destruction of the bronchial ciliated cells—there is nothing in the characteristic, thickened submucous coat in chronic bronchitis and asthma which is inconsistent with a non-inflammatory sero-cellular exudation due to neurovascular causes. The frequent association of chronic bronchitis with disorders of the autonomic nervous system—for instance, mucous colitis—commented on at the Annual Meeting of the British Medical Association in 1923 by Lord (then Sir Thomas) Horder, strengthens the thesis that chronic bronchitis is essentially a neurovascular disease. The anatomical relation of asthma and chronic bronchitis must be reviewed in their relation to each other and to the autonomic nervous system, and determined before the deeper biochemical problems as to basic causes are considered. Both diseases are illusive. Investigators need to be critical.

With regard to asthma, theories abound, probably all in some degree correct, and there are many who, in their eagerness to discover a new and specific cure, follow tracks which lead nowhere. The will-o'-the-wisp conducts inquirers in the direction of, and may approach close to, the truth, but it never reveals the actual sanctuary. I wonder whether Dr. Russell is following an asthma will-o'-the-wisp when he sets out to discover in the thyroid gland the *fons et origo mali*?—I am, etc.,

London, W.1, July 10th. J. B. CHRISTOPHERSON, M.D.

Vitamin A Deficiency in Childhood

SIR,—I have read with great interest Dr. Helen Mackay's article on vitamin A deficiency in children in the *Archives of Disease in Childhood*, to which you refer in your issue of June 30th. I would be glad if you would allow me to offer a criticism of this most important work.

The only diseases which were more prevalent among children not receiving extra vitamin A were lesions such as sore buttocks, sore scrotal skin or foreskin, intertrigo, dribbling eruptions, etc. These conditions are usually regarded as being largely due to lack of care and attention on the part of the mother or nurse, or, in Dr. Mackay's own words, "to some form of local irritation."

The physiological effect of the administration of special preparations, whether containing vitamins or not, has been admirably shown by Dr. Sutherland in his recent work on vitamins, where he found that in 80 per cent. of children fed on capsules containing no vitamins the parents considered that a marked improvement had taken place.

In Dr. Mackay's investigation is it not possible that the mothers, or those in attendance on the children, were conscious of the fact that their children were receiving special attention, as the vitamin A, in addition to being incorporated in the dried milk, was also given in the form of an emulsion? These parents would thus be expecting an improvement, which would result, perhaps unconsciously as far as they were concerned, in sufficient added attention to their children to give rise to the "statistically significant" improvement noted in their condition.—I am, etc.,

Slough, July 16th. W. H. S. WALLACE, M.D., D.P.H.

Barbiturate Poisoning

SIR,—Apropos of your review of the work of Professor Carrière and his associates on acute barbiturism, may I draw your attention to a recent article published by these workers (*C. R. Soc. de Biol.*, 1934, cxvi, 768). In this they deal with lesions observed in different organs post mortem. The severity and extent of the renal lesions are a function of the duration of the coma. Simple tumefaction is found in cases of brief duration. In animals treated with strychnine no difference in the intensity and general nature of the lesions was observed. On the contrary, acute pulmonary emphysema was found only in rabbits which had consumed large amounts of strychnine. Nothing is said of the influence of alcohol in this respect.—I am, etc.,

Paris, July 5th. D. T. BARRY.

Criticism of Ante-Natal Work

SIR,—The destructive criticism of the results of ante-natal work, by Mr. A. J. Wrigley (*Journal*, May 19th, p. S91), has been very timely, and the call for constructive criticism by Mr. Aleck Bourne (June 23rd, p. 1141) has stimulated me to express my views about ante-natal work in those cases which come under the classification of minor degrees of disproportion, and which often unnecessarily, as Mr. Wrigley has conclusively proved, undergo the procedure of premature induction of labour.

One of the defects in ante-natal work on these cases has been due to non-recognition of the fact that a large proportion of these potentially abnormal cases undergo a natural process of expansion of the pelvis, which converts them into potentially normal cases. Pelvimetry is one of the most important means of examining these cases, and, apart from a history of a previous normal labour at full term with a normal-sized foetus, it can only be out-classed by the methods of determining the relative proportion of the un moulded foetal head to the pelvis in the last five weeks of pregnancy. The result of the latter method will depend on the skill of the observer, and will only be possible in ante-natal clinics when the clinic accoucheur attends the childbirths himself. Hitherto, the clinic doctor usually has to rely on pelvimetry, other skeletal considerations, history of previous labours, etc.

The most reliable measurement in internal pelvimetry is the diagonal conjugate, but it is not a very easy procedure in primiparae, and the large number of women who object to internal examinations will go to the doctor who avoids these examinations. In external pelvimetry the most useful measurement is the external conjugate. This is the measurement to which I wish to draw attention.

It is generally taught that an external conjugate of less than seven inches indicates pelvic contraction in the majority of cases, and that with a further reduction of half an inch contraction is practically invariable. Six years ago a private patient of mine had a pelvis of the generally contracted type with an external conjugate of six and a half inches at two and a half months; at seven and a half months the external conjugate was seven inches. At thirty-seven weeks there was

apparent disproportion; medical premature induction failed; and stomach-tube induction at thirty-eight weeks ended in normal childbirth and a live child (6½ lb.). The following year I attended at the childbirth of the second baby, which weighed a little more than the first (7 lb.), and was born by the natural passages at full term without induction. Mother and children progressed normally. Early this year a similar primipara at two and a half months had an external conjugate of six and a quarter inches; at six and a half months the external conjugate measured seven inches, and, though the pelvis is of the generally contracted type, I am hoping for a normal natural delivery at full term without induction.

During the last six years I have repeatedly noted a growth of half an inch in the external conjugate during pregnancy; it may be due to stretching of the ligaments of the symphysis pubis and sacro-iliac joints, and some of the cases have complained of pain in the groins and hips relieved by lying down. Knowledge of this expansion of the pelvis during pregnancy may diminish considerably the number of premature inductions and diminish the consequent foetal mortality and maternal morbidity to which attention has been drawn. Before six years ago I used to limit my pelvimetry to an early date in pregnancy, and possibly ante-natal clinics are in the habit of doing the same.

I have searched the literature and can find no reference to anyone who has noted this increase of the external conjugate in any of the recent British or American textbooks of obstetrics or in Jarcho's book *The Pelvis in Obstetrics*, 1933. Owing to the care taken, I am convinced that the pelvic expansion is real and not due to increased adipose tissue or to flexion of the lumbar spine. The same increase will be noted if the posterior point of the pelvimeter is kept over the upper sacrum instead of the lower edge of the fifth lumbar spine.—I am, etc.,

E. HESKETH ROBERTS, F.R.C.S.Ed.

London, W 1, July 2nd

Traffic Control by Light Signals

SIR,—I was interested in Dr. Guy Bousfield's letter in the *Journal* of July 7th (p. 40) on the subject of traffic control lights, but I think that one or two points call for comment. I do not agree that a driver requires such lengthy warning of an intended stop as your correspondent suggests. Surely the mere fact that a signal-post is visible suggests the necessity of being prepared to stop and bringing the car "under control," though I trust that there are not many drivers who make a habit of going about with their cars out of control. Anyway, they will not do it for very long! I think that the present warning of the impending red stop signal is sufficient, but the period during which the amber is showing should be standardized.

If there are drivers with such a long reaction time as Dr. Bousfield suggests, surely they ought to give up driving altogether. If they are apt to fail at such a simple emergency as the traffic stop light it seems to me that they will be always having accidents, and belong to the class that Americans term "accident-prone."—I am, etc.,

London, S.E.15, July 9th

W. W. KING BROWN, M.B.

Evipan Anaesthesia

SIR,—I am now in entire agreement with Dr. Kuhne when he writes in your issue of July 7th (p. 40): "In the second instance evipan was acting on a centre already depressed by the premedication." The whole purpose of my previous letter was to suggest this, and I am satisfied that he has altered his opinion.—I am, etc.,

MONTAGUE SOLOMON, M.B., Ch.B., D.P.H.

Liverpool, July 7th.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

DISSOLUTION OF PARTNERSHIP

The partners can provide, in their agreement, for dissolution upon any terms they choose, but if they omit to do so the Act lays down the following regulations for dissolution.

If the partnership is entered into for a fixed term it is dissolved on the expiration of the term. If no term is fixed it is dissolved by any partner giving notice to the others of his intention to dissolve it. He may name a day for its dissolution: if he does not it is dissolved as from the date on which he communicates the notice. If any partner dies or goes bankrupt the partnership is dissolved as regards all the partners; and if any partner charges his share for his own debts the partnership may be dissolved at the option of the others. When a partner dies the survivors may collect and pay partnership debts, and may sue debtors without joining the representatives of the deceased partner as parties to the action. When a partner goes bankrupt the solvent partners may collect the partnership debts, and the trustees or assignees of the bankrupt can be restrained from interfering.

ILLEGAL PRACTICE

A partnership is dissolved by any event which makes the business unlawful, or makes it unlawful for the partners to carry it on together. It is probably illegal, as well as unethical, for a qualified and an unqualified person to agree to practise medicine in partnership (*Davies v. Mahama*, 1884), so such an alliance would not be recognized by law. If a member of a medical partnership had the misfortune to be removed from the *Register* by the General Medical Council under its penal jurisdiction, he could probably continue to practise without making the partnership illegal, but his partners would be liable to be struck off the *Register* for associating in practice with an unregistered practitioner. They would also be unable to sue for fees for the work he did. The court would probably consider the removal of a partner from the *Register* to be good ground for dissolving the partnership.

THE PARTNER OF UNSOUND MIND

The Act lays down several events in which the court may dissolve the partnership if one partner asks it to. If a partner is found lunatic by inquisition (a somewhat rare legal procedure), or is shown, to the satisfaction of the court, to be of permanently unsound mind, the court may decree a dissolution. In this case not only the other partners but also the insane partner, by his next friend or his "committee,"[†] has the right to ask that the partnership be dissolved. Lunacy does not of itself dissolve a partnership, and so long as the continuing partners elect to carry on in the hope that the insane member of the firm will recover there is no dissolution.

In *Jones v. Noy* (1833) the incapacitated partner, who died, had contracted to be always actively engaged in the business—that of a firm of solicitors. As the continuing partner was considered to have carried on in the hope of the other's recovery the representatives of the incapacitated partner were held entitled to his share of the profits.

Unless the sick partner has been found lunatic by inquisition the court will only dissolve the partnership if it is satisfied that his incapacity is permanent—not an easy question for a psychiatrist to answer on oath. If the partner has no active duties to perform the court will probably not dissolve on the application of any other partner. A partner of unsound mind might seriously injure the business of a medical firm if he were permitted to

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), the second on June 23rd (p. 1145), and the third on July 7th (p. 42).

† The legal guardian of a person who has been found lunatic by inquisition.

interfere with it, and the position of the other partners when one of the firm contracts mental disease is no enviable one. It is hardly possible to imagine a more urgent and delicate situation. To certify him themselves would impose on them a responsibility of the first magnitude, and bring upon them the gravest suspicion of the court; yet they might justify their action if the urgency were great, and if they had taken scrupulous care to have their judgement confirmed immediately by independent and expert practitioners—and also to preserve the ailing partner's interest in the business—and if they had immediately and frankly disclosed the facts to their partner's relatives. The fundamental question the court applies to all partnership transactions is: Did you safeguard your partner's interests as scrupulously as your own? For obvious reasons a certifiably insane partner offers less difficulty than one whose eccentricity is less patent. If the other partners can produce good evidence that their colleague is damaging the partnership by his conduct they may succeed in obtaining an injunction to restrain him from interfering in the partnership affairs; but the evidence must be good and may be very difficult to present to a judge necessarily unaccustomed to medical practice. The important point is that the court will not be interested in the medical condition *per se* of the sick partner, but only in the effect which his conduct is likely to have on the practice. The proof, therefore, should be kept on a basis of conduct, and the question whether the partner is or is not of unsound mind—whatever that may mean—is left for determination by other authority.

INCAPACITY AND MISCONDUCT

The court may also decree dissolution when a partner becomes permanently incapable, from any cause other than lunacy, of performing his part of the partnership contract; or when a partner has been guilty of conduct calculated to prejudice the carrying-on of the business; or has wilfully or persistently committed a breach of the agreement; or has so conducted himself that it is not reasonably practicable for the other partners to carry on business with him. The court may dissolve a partnership when it can only be carried on at a loss, and has general discretion to dissolve partnerships when circumstances have arisen which seem to make dissolution just and equitable. Before the Act was passed, in 1890, the court used to inquire chiefly whether the conduct complained of was likely to destroy mutual confidence between the partners, but the Act permits it to ask also whether the conduct is likely to prejudice the welfare of the business and shake its public credit. In every case the nature of the particular business is all-important. It is, for instance, highly probable that the court would dissolve a medical partnership because one of the partners had been guilty of sexual immorality, for such conduct must be very damaging to the firm.

A doctor complained to his defence society* that his partner had been cited as co-respondent in divorce proceedings, had been found to have committed adultery, and was openly living with the respondent. He was rightly advised that this conduct would be likely to cause serious injury to the practice, and that he would be justified in giving notice terminating the partnership under the clause in the articles dealing with misconduct.

In this case, of course, the aggrieved partner could have pleaded that the other had broken the written agreement, and would not have had to rely on the terms of the Act. The court would, however, in interpreting the misconduct in the articles, apply the same standards as if it were deciding whether misconduct had been committed in the sense of the Act. Nevertheless, the court will not interfere merely because a partner has committed a trivial departure from duty, or a technical violation of the articles, or some minor misconduct. Courts of equity do not allow a party to a contract to take unreasonable advantage of the letter of an agreement, and it is necessary to show grave damage to mutual confidence or to the good name of the firm.

TEST FOR LIVE BIRTH IN CASES OF INFANTICIDE BY DROWNING

When the dead body of a newly born infant found in a waterway is the subject of medico-legal examination the first point to be dealt with is, Was the infant born alive? The answer to this question depends on the state of maturity of the infant, the volume and colour of the lungs, the flotation test, the contents of the stomach, etc.¹ On the Continent, however, great importance is laid on the contents of the bowel below the pylorus.

Fagerlung² states that the presence of water or foreign material from the waterway is definite evidence of live birth, and furthermore, it is definite evidence that the infant was alive when it entered the water. He immersed the bodies of stillborn infants in water for from seven to forty-three hours, and in no instance did he observe any of the water below the pylorus. Experiments on the same lines have been carried out by Beothy,³ and these confirm the fact that no water can pass the pylorus unless there has been life. Beothy dealt with twenty-four cases, in which he removed the stomach and filled it under pressure with water coloured with carbo-fuchsin or methylene-blue. In none of his cases did any of the fluid pass the pylorus.

From these experiments, therefore, it would appear that if water or any foreign material from the waterway be found below the pylorus it is definite evidence of live birth.

Universities and Colleges

UNIVERSITY OF OXFORD

The Board has recommended to the Vice-Chancellor that the Theodore Williams Scholarship in Human Anatomy, 1934, be divided between D. L. P. de Courcy, New College, and L. L. Whythead, Oriel College. This will necessitate the passing of a decree.

The Master and Fellows of University College, upon the report of the professor of pharmacology, have awarded the Radcliffe Scholarship in Pharmacology to H. M. Sinclair, B.A., B.Sc., Oriel College.

The Welsh Prize for excellence in anatomical drawing has been awarded to A. Austen Hall, Magdalen College.

At a congregation held on July 14th the following medical degrees were conferred:

D.M.—R. S. B. Pearson.

M.Ch.—H. F. Hoesley.

B.M.—J. H. Bartlett, D. W. Geidt, W. H. A. Picton, C. E. Greenwood, R. I. Bence, T. W. Lloyd, A. M. G. Campbell, R. H. Gardiner, C. A. Boucher.

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—(Part I): M. Kahn, N. G. Moitra. (Part II): T. R. Harlan, M. S. Kavarana, A. U. Mullar, N. G. Moitra, G. R. Nolan, W. O'Neill, J. P. Raban, C. W. Robertson, T. F. Tierney.

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

M.S.—(Branch I, Surgery): G. V. W. Anderson, A. W. Kendall, D. Trevor (University Medal), H. L.-C. Wood.

UNIVERSITY COLLEGE

The following awards have been made in the Faculty of Medical Sciences:

Entrance Scholarship, L. J. Temple; Entrance Exhibitions, R. Mawson, W. S. Levin; Sharpey Scholarship (Physiology), D. H. K. Lee, M.Sc., M.B., B.S.; Anatomy (Senior Class—Gold Medal), Nancy E. G. Richardson; Physiology (Senior Course—Gold Medal), M. Albert.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

The following candidates have been approved at the examination indicated:

ACADEMIC POST-GRADUATE DIPLOMA IN PUBLIC HEALTH.—O. M. Akhiani, O. M. T. Ansari, K. P. Beaubrun, Catherine B. Crane, W. H. Crichton, F. R. Danson, H. A. Dickze, Margaret L. Foxwell, Muriel O. Gibson, J. B. Great Rev, G. S. C. de S. Gueskera, Ellen G. Heycock, G. Holroyd, F. E. Lipscomb, F. J. G. Lashman, G. H. Lowe, G. P. McC. Marshall, K. J. G. Milne, D. D. Payne, Ethel A. Perrott, C. D. Preston, *Abson J. Rae, L. B. E. Seneviratne, Mary Sutcliffe, L. G. W. Urich, M. H. Wace, E. C. P. Williams, *S. L. Wright. (Part II): Muriel V. Joscelyne, Hyacinth I. Lightbourne, I. A. MacDougall.

* Awarded a mark of distinction.

UNIVERSITY OF LIVERPOOL

The following awards have been made in the Faculty of Medicine. *John Rankin Fellowships in Anatomy*, (Senior) Dr. A. G. Leigh, (Junior) Dr. R. A. Hughes. *Johnston Colonial Fellowship in Biochemistry*, G. R. Tristram. *Robert Gee Fellowship in Human Anatomy*, Dr. A. J. Hellet. *Holt Fellowship in Pathology*, Dr. C. S. Anderson. *Holt Fellowship in Physiology*, Dr. J. G. Hailwood. *Thelwall Thomas Fellowship in Surgical Pathology*, Dr. A. S. Kerr. *John W. Garrett International Fellowship in Bacteriology*, Dr. E. R. Jones. *Ethel Boyce Fellowship in Gynaecology*, Dr. J. Polonsky. *University Graduate Scholarship*, H. F. Harwood. *Honorary Scholarship*, L. Henry. *Samuels Memorial Scholarships*: (Medicine) Dr. J. Libman, (Surgery) Mr. M. Silverstone, (Obstetrics and Gynaecology) Dr. J. Polonsky. *Junior Lyon-Jones Scholarship*, Frances E. Brierton. *William Mitchell Banks Bronze Medal (Anatomy)*, E. L. Salinger. *Kanthack Medal (Pathology)*, H. R. W. Lunt. *Silver Medal for Forensic Medicine and Toxicology*, V. K. Brennan; *proxime accessit*, A. C. Brewer, A. Cohen. *Gold Medal for Public Health*, V. K. Brennan. *Silver Medal for Pharmacology*, A. J. Gill; *proxime accessit*, A. Singer. *George Adam Prize in Pathology*, H. F. Harwood. *Owen T. Williams Prize*, Margaret F. Procter.

The Council, on July 11th, appointed Dr. D. B. Blacklock, Walter Myers professor of parasitology in the University since 1929, to the newly instituted Chair of Tropical Hygiene, and T. Southwell, D.Sc., Ph.D., lecturer in helminthology in the Liverpool School of Tropical Medicine, as lecturer in parasitology in the University, both from October 1st.

UNIVERSITY OF SHEFFIELD

Dr. F. E. E. Schneider, medical superintendent of Rampton State Institution, has been appointed assistant lecturer in mental diseases. Dr. R. T. Cooke has been appointed junior assistant bacteriologist.

The following candidates have been approved at the examination indicated.

FIRST MB, ChB.—Part II. Kathleen M. Adamson and M. B. Brady (with second-class honours), J. K. A. Beverley, T. Lodge, G. F. E. Ramsden, H. R. Vickers, W. D. Wallace.

UNIVERSITY OF ABERDEEN

The following degrees were conferred at a graduation on July 9th:

MD.—T. N. Morgan, *Ann L. Thomson, †A. Cruickshank, †J. R. M. Mackie, †A. G. Badenoch, †R. Mackay, E. Farquharson, †A. Fraser, W. H. Harris, A. W. Henderson, Catherine I. A. Jamieson-Craig, Mary Riddoch.

MB, ChB.—C. Ludwig (second-class honours), E. P. Adel, A. J. Beddie, H. Burnett, J. R. Byars, J. Cameron, E. Cay, E. M. Darnley, I. K. Etkin, Jane R. Forgie, C. Glassman, J. F. R. Goodlad, J. T. Grassie, D. Horn, J. R. Horn, R. A. Horne, P. W. Ingram, M. H. Kirsner, A. H. Lavelle, L. A. Ledingham, A. P. Macdonald, J. C. McGregor, D. A. M. MacLennan, J. H. S. Morgan, A. F. T. Ord, G. Parker, J. R. M. Sangster, I. M. Schner, J. A. Shreier, I. Shechner, S. R. N. Smith, E. J. Strachan, J. W. M. Sutherland, A. H. Weiner.

D.Ph.—A. G. Badenoch, D. Bell, Alexandra H. Duthie (née Benton), J. B. Ewen.

* Awarded highest honours for thesis. † Awarded honours for thesis. ‡ Awarded commendation for thesis.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly meeting of the Council of the Royal College of Surgeons of England was held on July 12th.

Sir Holburt Waring was re-elected President, and Mr. Wilfred Trotter, F.R.S., and Mr. A. H. Burgess were elected Vice-Presidents.

Professor William Wright (anatomy) and Professor John Mellanby (physiology) were appointed to conduct a Primary Examination for the Fellowship at Madras in December, 1934.

The following lecturers were appointed for the ensuing year:

Hunterian Professors.—Mr. Harold Burrows, C.B.E., one lecture on Some Observations on the Sex Hormones in Relationship to Surgical Pathology; Mr. C. Max Page, D.S.O., one lecture on the Late Results of the Operative Treatment of Osteoarthritis; Mr. W. Rowley Hirstow, one lecture on Internal Derangement of the Knee-joint; Mr. T. Pomfret Kilner, one lecture on the Transplantation of Skin; Mr. Laurence O'Shaughnessy, one lecture on the Surgery of the Lung Root; Mr. H. J. Seddon one lecture on the Morbid Anatomy of Caries of the Thoracic Spine in Relation to Treatment; Mr. B. W. Rycroft, one lecture on Recent Investigations in the Aetiology and Treatment of Glaucoma; Mr. G. C. Knight, one lecture on the Innervation of the Oesophagus in Relation to the Surgical Treatment of Achalasia of the Cardia; Mr. Lambert Rogers, one lecture on the Surgery of Spinal Tumours; Mr. C. Bowdler Henry, one lecture on the Aetiology and Treatment of Misplaced Third Molars; Dr. Macdonald Critchley, one lecture on the Morphology of the Cerebro-spinal Arteries and their Clinical Significance; Dr. James F. Bradford, one lecture on Dystrophies of the Skeleton.

Arns and Gale Lecturer.—Dr. John Beattie, three lectures on the Anatomy and Physiology of the Hypothalamus: (1) the central mechanism controlling the cardiovascular system; (2) the relation of the hypothalamus to the gastro-intestinal tract; (3) the nervous control of metabolism and the relation of the pituitary gland to the hypothalamus.

Erasmus Wilson Lecturers.—Mr. R. Davis-Colley, C.M.G., Mr. C. E. Shattock, Mr. Cecil P. G. Wakley, and Mr. E. K. Martin, one demonstration each on Pathology; Mr. T. B. Layton, D.S.O., one demonstration on the Rhinological (or Nasal) Aspects of (or Problems in) Mummification, Mr. Ronald W. Raven, one demonstration on Abnormalities of Surgical Importance resulting from the Persistence of Rudimentary Embryological Structures.

Arnott Demonstrator.—Dr. John Beattie, Six demonstrations on the contents of the Museum.

Sir Frank Colyer, K.B.E. (honorary curator of the Odontological Collection), and Mr. C. J. S. Thompson, M.B.E. (honorary curator of the Historical Collection) were re-appointed for the ensuing year. Mrs M. L. Tildesley was reappointed curator of the Department of Human Osteology for the next six months.

The Hallett Prize for Anatomy and Physiology was awarded to David Lloyd Griffiths, M.B., Ch.B., of Manchester; and the fifth MacLoughlin Scholarship of £120 per annum was awarded to Joseph Francis Smith of Bristol Grammar School.

Diplomas were granted jointly with the Royal College of Physicians as follows:

DIPLOMA IN PRINCIPLES OF MEDICINE.—S. M. Ab, J. H. Dobbin, P. B. Lee Potter, E. K. Patchard, J. M. Rose, A. T. G. Thomas.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—G. J. Allan, K. W. Allen, J. N. Atkinson, G. I. Barnes, I. S. Bhalley, R. H. P. Clark, F. J. Copeland, A. P. Davis, S. B. Dimson, H. Erston, P. S. Gowerdardene, A. C. de B. Helme, N. M. James, W. B. Johnston, F. H. Reynolds, M. Shun-Shun, C. H. Yeoh.

DIPLOMA IN ORTHOPAEDIC MEDICINE AND SURGERY.—E. D. Anklesaria, R. U. Gillan, G. Gordon-Nigier, T. R. Jansen, A. H. Lowther, D. W. McLean, L. H. Motter, M. M. Parikh, A. A. Pomfret, K. Rai, D. Ram, W. E. Rutledge, A. C. Shuttleworth, S. B. Smith, M. M. Sydlun, C. Taylor.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—H. E. C. Adelt, C. N. Atlee, A. Balke, L. T. Hilliard, S. G. June, Madeline R. Lockwood, J. Mackay, F. E. Pilkington, C. H. Swanton, A. H. Wilson.

DIPLOMA IN LUNACY AND SURGERY.—S. K. N. Chowdhury, R. Howarth, A. R. Khan, D. Loing, W. B. McKelvie, C. E. S. Osby, J. A. Tumarkin.

DIPLOMA IN MEDICAL RADIOLOGY.—J. E. Blawett, P. Hogan, W. H. Hooton, A. H. Richardson, A. M. Vlek.

COMBINED SCHOLARSHIPS EXAMINATION

As the result of the combined hospitals scholarships (Guy's, St. Bartholomew's, and St. Thomas's), the following scholarships and exhibitions have been awarded:

Guy's Hospital Medical School: University Scholarship, E. B. French (St. John's College, Cambridge); Exhibition, R. G. Blackledge (New College, Oxford).

St. Bartholomew's Hospital Medical College: University Scholarship, D. I. Crowther (Magdalen College, Oxford); Exhibition, P. F. Barwood (Sidney Sussex College, Cambridge).

St. Thomas's Hospital Medical School: University Scholarship, T. J. Fairbank (Trinity College, Cambridge); Exhibition, J. Sutcliffe (St. John's College, Cambridge).

interfere with it, and the position of the other partners when one of the firm contracts mental disease is no enviable one. It is hardly possible to imagine a more urgent and delicate situation. To certify him themselves would impose on them a responsibility of the first magnitude, and bring upon them the gravest suspicion of the court; yet they might justify their action if the urgency were great, and if they had taken scrupulous care to have their judgement confirmed immediately by independent and expert practitioners—and also to preserve the ailing partner's interest in the business—and if they had immediately and frankly disclosed the facts to their partner's relatives. The fundamental question the court applies to all partnership transactions is: Did you safeguard your partner's interests as scrupulously as your own? For obvious reasons a certifiably insane partner offers less difficulty than one whose eccentricity is less patent. If the other partners can produce good evidence that their colleague is damaging the partnership by his conduct they may succeed in obtaining an injunction to restrain him from interfering in the partnership affairs; but the evidence must be good and may be very difficult to present to a judge necessarily unaccustomed to medical practice. The important point is that the court will not be interested in the medical condition *per se* of the sick partner, but only in the effect which his conduct is likely to have on the practice. The proof, therefore, should be kept on a basis of conduct, and the question whether the partner is or is not of unsound mind—whatever that may mean—is left for determination by other authority.

INCAPACITY AND MISCONDUCT

The court may also decree dissolution when a partner becomes permanently incapable, from any cause other than lunacy, of performing his part of the partnership contract; or when a partner has been guilty of conduct calculated to prejudice the carrying-on of the business; or has wilfully or persistently committed a breach of the agreement; or has so conducted himself that it is not reasonably practicable for the other partners to carry on business with him. The court may dissolve a partnership when it can only be carried on at a loss, and has general discretion to dissolve partnerships when circumstances have arisen which seem to make dissolution just and equitable. Before the Act was passed, in 1890, the court used to inquire chiefly whether the conduct complained of was likely to destroy mutual confidence between the partners, but the Act permits it to ask also whether the conduct is likely to prejudice the welfare of the business and shake its public credit. In every case the nature of the particular business is all-important. It is, for instance, highly probable that the court would dissolve a medical partnership because one of the partners had been guilty of sexual immorality, for such conduct must be very damaging to the firm.

A doctor complained to his defence society* that his partner had been cited as co-respondent in divorce proceedings, had been found to have committed adultery, and was openly living with the respondent. He was rightly advised that this conduct would be likely to cause serious injury to the practice, and that he would be justified in giving notice terminating the partnership under the clause in the articles dealing with misconduct.

In this case, of course, the aggrieved partner could have pleaded that the other had broken the written agreement, and would not have had to rely on the terms of the Act. The court would, however, in interpreting the misconduct in the articles, apply the same standards as if it were deciding whether misconduct had been committed in the sense of the Act. Nevertheless, the court will not interfere merely because a partner has committed a trivial departure from duty, or a technical violation of the articles, or some minor misconduct. Courts of equity do not allow a party to a contract to take unreasonable advantage of the letter of an agreement, and it is necessary to show grave damage to mutual confidence or to the good name of the firm.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly meeting of the Council of the Royal College of Surgeons of England was held on July 12th.

Sir Holburn Waring was re-elected President, and Mr. Wilfrid Trotter, F.R.S., and Mr. A. H. Burgess were elected Vice-Presidents.

Professor William Wright (anatomy) and Professor John Mellanby (physiology) were appointed to conduct a Primary Examination for the Fellowship at Madras in December, 1934.

The following lecturers were appointed for the ensuing year:

Hunterian Professors.—Mr. Harold Burrows, C.B.E., one lecture on Some Observations on the Sex Hormones in Relationship to Surgical Pathology; Mr. C. Max Page, D.S.O., one lecture on the Late Results of the Operative Treatment of Osteoarthritis; Mr. W. Rowley Bristow, one lecture on Internal Derangement of the Knee-joint; Mr. T. Pomfret Kilner, one lecture on the Transplantation of Skin; Mr. Laurence O'Shaughnessy, one lecture on the Surgery of the Lung Root; Mr. H. J. Seddon one lecture on the Morbid Anatomy of Caries of the Thoracic Spine in Relation to Treatment; Mr. B. W. Rycroft, one lecture on Recent Investigations in the Aetiology and Treatment of Glaucoma; Mr. G. C. Knight, one lecture on the Innervation of the Oesophagus in Relation to the Surgical Treatment of Achalasia of the Cardia; Mr. Lambert Rogers, one lecture on the Surgery of Spinal Tumours; Mr. C. Bowdler Henry, one lecture on the Aetiology and Treatment of Displaced Third Molars; Dr. Macdonald Critchley, one lecture on the Morphology of the Cerebro-spinal Arteries and their Clinical Significance; Dr. James F. Brailsford, one lecture on Dystrophies of the Skeleton.

Arris and Gale Lecturer.—Dr. John Beattie, three lectures on the Anatomy and Physiology of the Hypothalamus: (1) the central mechanism controlling the cardiovascular system; (2) the relation of the hypothalamus to the gastro-intestinal tract; (3) the nervous control of metabolism and the relation of the pituitary gland to the hypothalamus.

Erasmus Wilson Lecturers.—Mr. R. Davies-Colley, C.M.G., Mr. C. E. Shattock, Mr. Cecil P. G. Wakeley, and Mr. E. K. Martin, one demonstration each on Pathology; Mr. T. B. Layton, D.S.O., one demonstration on the Rhinological (or Nasal) Aspects of (or Problems in) Mummification; Mr. Ronald W. Raven, one demonstration on Abnormalities of Surgical Importance resulting from the Persistence of Rudimentary Embryological Structures.

Arnott Demonstrator.—Dr. John Beattie, Six demonstrations on the contents of the Museum.

Sir Frank Colyer, K.B.E. (honorary curator of the Odontological Collection), and Mr. C. J. S. Thompson, M.B.E. (honorary curator of the Historical Collection) were re-appointed for the ensuing year. Miss M. L. Tildesley was reappointed curator of the Department of Human Osteology for the next six months.

The Hallett Prize for Anatomy and Physiology was awarded to David Lloyd Griffiths, M.B., Ch.B., of Manchester; and the fifth MacLoughlin Scholarship of £120 per annum was awarded to Joseph Francis Smith of Bristol Grammar School.

Diplomas were granted jointly with the Royal College of Physicians as follows:

DIPLOMA IN PUBLIC HEALTH.—S. M. Ali, J. H. Dobbin, P. B. Lee Potter, E. K. Pritchard, J. M. Reese, A. T. G. Thomas.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—G. J. Allan, K. W. Allen, J. N. Atkinson, G. T. Barnes, I. S. Bhalla, R. H. P. Clark, F. J. Copeland, A. P. Davis, S. B. Dimson, H. Epstein, P. S. Goonewardene, A. C. de Helme, N. M. James, W. B. Johnston, F. H. Reynolds, M. Shun-Shin, C. H. Yeoh.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—E. D. Anklesaria, R. U. Gillan, G. Gordon-Napier, T. R. Jansen, A. H. Lowther, D. W. McLean, L. H. Mottet, M. M. Parikh, A. A. Pomfret, K. Rai, D. Ram, W. E. Rutledge, A. C. Shuttleworth, S. B. Smith, M. M. Sydnin, C. Taylor.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—H. E. C. Aslett, C. N. Atdee, A. Baldie, L. T. Hilliard, S. G. James, Madeline R. Lockwood, J. Mackay, F. E. Pilkington, C. H. Swanton, A. H. Wilson.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—S. K. N. Chowdhury, R. Howarth, A. R. Khan, D. Laing, W. B. McKelvie, C. E. S. Oxley, J. A. Tumarkin.

DIPLOMA IN MEDICAL RADIOLOGY.—J. E. Blewett, P. Hogan, W. H. Hooton, A. H. Richardson, A. M. Vick.

COMBINED SCHOLARSHIPS EXAMINATION

As the result of the combined hospitals scholarships (Guy's, St. Bartholomew's, and St. Thomas's), the following scholarships and exhibitions have been awarded:

Guy's Hospital Medical School: University Scholarship, E. B. French (St. John's College, Cambridge); Exhibition, R. G. Blackledge (New College, Oxford).

St. Bartholomew's Hospital Medical College: University Scholarship, D. I. Crowther (Magdalen College, Oxford); Exhibition, P. F. Barwood (Sidney Sussex College, Cambridge).

St. Thomas's Hospital Medical School: University Scholarship, T. J. Fairbank (Trinity College, Cambridge); Exhibition, J. Sutcliffe (St. John's College, Cambridge).

Obituary

W. W. KING, F.R.C.S.ED., F.C.O.G.

Surgeon, Jessop Hospital for Women, Sheffield

We regret to announce the death, on July 9th, of Mr. William Wilfrid King at the age of 52. He was educated at Stonyhurst and the Bristol Medical School, whence he qualified M.R.C.S., L.R.C.P. in 1906, subsequently taking the Edinburgh Fellowship in 1908, and, on the formation of Bristol University, the M.B. of that university.

Mr. King went to the Royal Hospital, Sheffield, almost immediately after qualification, and was soon recognized by the contemporary generation of "housemen" in the various hospitals of the city as a man of exceptional energy, ability, and what is known as character. As a house-surgeon at the Jessop Hospital for Women, and later as surgical registrar at that institution, he showed a special aptitude for gynaecology and obstetrics, and in addition to winning the esteem of the honorary staff he also began to become known among the practitioners in the city. When a vacancy occurred on the staff of the Jessop it was assumed by most that King would be appointed, but he was passed over, and it was a great blow to him. Crippled by the absence of private means, King had to make a very momentous decision: to stay in the city and await another vacancy. Those were not the days when the hospitals and universities nursed young consultants. King had to find some means of subsistence whilst he besieged the gynaecological citadel. He was known to have had a good laboratory training, and the Royal Infirmary staff asked him to apply for the part-time post of clinical pathologist at the meagre salary of £75 a year; protesting with characteristic candour that his aim was not pathology, he applied for the post and was appointed (1911); he was a great success. In the old clinical laboratory of the Infirmary he slogged away with inadequate equipment—helped by a B.M.A. grant—in an attempt to elucidate the toxæmias of pregnancy, and his first important paper was on the Abderhalden reaction for pregnancy. Then came the war, and he at once joined the R.A.M.C., being attached to the Third Northern General Hospital. King was never passed for general service, and remained in the city for the duration of the war. His capacity for work was truly colossal. It did not seem to matter what it was: he did any amount of work in the laboratory—chiefly in connexion with the search for typhoid and dysentery carriers—and in addition he tackled all kinds of surgery, and found time to rush out and see a few patients on behalf of colleagues who were over-seas. Somewhere about the end of the war he became a member of the staff at the Jessop Hospital for Women, and immediately began to pull his full weight. He spent much time studying the pathology and clinical features of pelvic adenomyomata, but the great interest of his life turned out to be the aetiology of puerperal sepsis. King was in charge of a large municipal maternity home, and, as is well known, has taken a large part in the attempt to correlate streptococcal infections of the throat with puerperal sepsis. Indeed, this work was probably the cause of his premature death: he went out to investigate an outbreak of sepsis in a neighbouring town, and about forty-eight hours later was himself attacked by a tonsillar infection with *Streptococcus haemolyticus*, which eventually, through infection of the deep veins of the neck, proved fatal.

As a teacher King was excellent, but his own rapid thought and sincerity of purpose did not fit him to tolerate fools. Rapidity of thought and action were characteristic of the man in all his activities. He was

a great surgeon, cut off just as he had attained success and reputation. His untimely death will be an immense loss to his hospital and university, which had every right to expect another ten years of active service. The local profession has lost a wise counsellor, not only on matters gynaecological, but on medico-political affairs, as shown by his tenure of the chairmanship of the United Hospitals Staff Club and of the Sheffield Division of the British Medical Association.

No notice of King's life would be complete without reference to his religion, as he was a sincere Catholic who took part in all activities of the Church open to the layman. He leaves a widow and four children.

A. E. B.

BRENNAN DYBALL, F.R.C.S.

Surgeon, Royal Devon and Exeter Hospital

By the unexpected and untimely death of Mr. Brennan Dyball of Exeter, at the age of 62, the West Country has lost one of its foremost surgeons. After a distinguished career as a student, when he became a gold medallist in surgery and gained the Beane Scholarship in that subject, he went to Exeter in 1898 with a great reputation from St. Thomas's Hospital, and from the Leeds School, where he had been resident surgical officer at the General Infirmary. At the time of his death, at his moorland bungalow, he had for long commanded the respect and affection of all his colleagues and of the profession generally.

By disposition modest and retiring, and hating publicity in any shape—for example, no one ever succeeded in persuading Dyball to take the chair at a professional dinner—he was yet recognized by all who came in contact with him as an outstanding instance of the rare combination of high and widely cultured intellectual gifts, soundly balanced vision and judgement, and a meticulous mind for the smallest detail of any work or scheme, large or small, which he took up. Moreover, he excelled as a carpenter and as a motor-car technician. Of physique ideal for his work, he was full surgeon to the Royal Devon and Exeter Hospital for twenty-one years, for the last twelve of which he was the senior; and from the first set a standard of study and technique worthy for all to aim at, and not only maintained that standard to the end, but was for ever ceaselessly seeking to improve it. His active and eager mind was always out for the best of the latest methods. His approach to a case was that of a physician, and every side of a problem received full consideration before a decision was reached. A man of very few words, he yet, by his manifest kindness and understanding, held the fullest confidence of his patients of all classes, among whom must be included an exceptionally large number of doctors and their families; and, though not rich, he was notoriously, indeed sometimes embarrassingly, indifferent to the financial reward of his labours.

Mr. Dyball acted as honorary secretary of the Section of Surgery at the British Medical Association's meeting at Exeter in 1907. Early during the war he was given a commission in the R.A.M.C. (T.), but, being indispensable at home, was seconded to take charge of No. 5 Section of Exeter War Hospitals, a hospital of over 200 beds, the whole of the surgical work of which he carried out; in addition to his work at the Royal Devon and Exeter Hospital and a large private practice. But the outstanding public fruit of his prevision was the establishment of the orthopaedic organization throughout Devon, centred at the Princess Elizabeth Orthopaedic Hospital; and by general consent the whole credit for this work must be equally divided between him and, on the lay side, Dame Georgiana Buller. And, having envisaged it, Dyball characteristically designed it, not only as to general

layout but down to the smallest detail, and plunged whole-heartedly into every aspect of the institution of this new service, from the active surgical work of which he at once retired when it became possible to appoint a whole-time specialist in this branch. His creative skill found scarcely less opportunity for full play in the many improvements and large additions to the Royal Devon and Exeter Hospital since the war, some long accomplished and others now under construction or as yet only designed in detail which he was destined not to see, but all of which bear the manifest imprint of his influence and skill, as all engaged with him in the committee work would readily testify.

The colleague to whom we are indebted for this memoir adds: In Dyball the profession has lost a man who was generally beloved and who combined powers of independent and original practical thought with manual dexterity, and it is not too much to say that the whole county mourns his loss.

THE LATE MR. BERNARD CRIDLAND

D. S. S. writes: As one of the number of residents whose privilege it has been from time to time to work with and for Mr. Bernard Cridland, I would like to add to the many that you will have received my appreciation of his unfailing kindness to his juniors. In particular he maintained an interest in the future of the many younger members of the specialty to whom in their hospital days he so freely imparted information and help, and encouragement to emulate his operative skill. Though he set himself and his residents a high standard of perfection, he was more than charitable to one's constant failures to attain it. His hospitality, generosity, and courtesy will be long remembered and appreciated by all who had the opportunity of personal contact with him, and his influence will continue to be felt for many years. Since leaving his immediate supervision I have had many occasions to be grateful to him for his considered opinions on matters of every kind, and his juniors have lost not only a revered and respected chief, but a very good friend.

THE LATE SIR JAMES FOWLER

Dr. REGINALD HEARN writes: I feel that I may have something of interest to add to your obituary notice of that gracious personality the late Sir James Fowler. He and I, since my election in 1924, were the only medical members of the Beefsteak Club. He loved the place, and not only visited it in former years, as you correctly state, but continued to dine there with the utmost regularity until the latter part of 1933. He then told me with uncanny accuracy that he had only a short time in which to live, that this was his last visit, and that he intended at the end of the year to resign from the club after a membership of nearly fifty years. At the Beefsteak everyone dines at the same table, and conversation is general. In the vast majority of cases its members are prominent and distinguished in most varying walks of life; but in our profession we all know the stupid manner in which even the most intelligent layman will occasionally attempt to discuss the technical side of medicine with a doctor. Fowler hated it, and the whimsical, kindly, albeit sometimes cutting manner in which he repelled all such attempts was a joy to behold. This side of him only appeared when laymen were present. If, as often happened, we were alone together, he would delight in giving me the benefit of his rich professional experience, and I only hope that I may have benefited from it. Such occasions would be late in the evening after other members had left, for he was always a late diner, and going early to bed did not appeal to him. His great friendship with his fellow member Lord Montagu was formed at the Beefsteak, and the associations with Beaulieu which resulted from it were the delight of his later years. His general culture was wide and profound, which rendered his conversation fascinating. About him there seemed to cling the atmosphere of the more spacious and leisured age

which he represented, and in his passing we have to mourn one who was, in the truest sense of the term, a "scholar-physician" of a rare and splendid type.

Dr. ARTHUR F. PERIGAL, New Barnet, writes: I was fortunate to be one of Kingston Fowler's house-physicians at Brompton thirty-four years ago, and learned much by his meticulous and thorough examination of patients and his accurate deductions therefrom, albeit street noises were often distracting, causing him to remark upon the difficulty of auscultating to the accompaniment of popular tunes of the day! He had a charming and genial manner which made consultations with him a pleasure, and his kindness I have never forgotten.

Dr. DAVID CHARLES LLOYD, the tuberculosis officer for Cardiganshire under the Welsh National Memorial Association, died at his home in Lampeter on June 26th after only a day's illness. A native of Corwen, North Wales, and a student at Guy's Hospital, after qualifying in 1911 he went into general practice at Llanfairfechan, where he remained for three years. His knowledge of the work and the trials and difficulties of general practitioners stood him in good stead later on in establishing cordial relations with his colleagues in practice. The Welsh National Memorial Association, for the prevention, treatment, and abolition of tuberculosis in Wales, was incorporated by Royal Charter in 1912. To an ardent Welshman fresh from hospital work this national effort to stamp out a national scourge made an immense appeal. From quite an early date Lloyd was co-operating with the tuberculosis physician for his area and consulting with him on cases met with in his own practice. From this interest grew what was to become a life-long passion—the fight against tuberculosis. In 1915 he entered into the service of the Memorial Association and came under the stimulating influence of Dr. Marcus Paterson, and learnt to apply the basic principles of the treatment of tuberculosis laid down by the latter. After various appointments under the association, Dr. Lloyd became a tuberculosis physician for Cardiganshire, and after his eighteen years in the county it is difficult to think of Cardiganshire without thinking of him. Those who have been engaged in tuberculosis work realize the long uphill fight which took place in the early days before the subject received adequate recognition; the long struggle against prejudice, ignorance, and superstition. The work was exacting and the discouragements many, and those devoting themselves to it were of the nature of pioneers. In a pioneer we expect ability allied to fearlessness, tenacity, and self-sacrifice. The pioneer must live with and for his work. In medicine we expect to find in addition sympathy and understanding. The work is important, but must never be allowed to submerge the patient. Dr. Lloyd had all these qualities combined with a receptive mind, always open to new knowledge, and ever ready to apply what was useful to the treatment of his patients. He was generous in giving credit to others, and, although disclaiming any credit to himself, had the satisfaction of seeing the death rate in his own county fall from 157 to 66 in a period of twenty years. To his patients he was physician, counsellor, and friend, and in his dealings with them never forgot they had minds as well as bodies. He lived a full and strenuous life, and the manner of his going was such as he would have wished—to go when still actively engaged in the work he loved so much.

H. A. R.

We regret to announce the death, on July 15th, as the result of a motor accident, of Dr. ROBERT HERVE YELF of Norwich. Both his father, Dr. R. E. B. Yelf, now of Selsey and a past-president of the Oxford and Reading Branch of the B.M.A., and his grandfather, the late J. L. K. Yelf, were medical practitioners at Moreton-in-Marsh Gloucestershire. He was educated at Rossall School, served during the Great War as Lieutenant in the 24th Royal Lancashire Regiment, and was badly wounded. He studied for the medical profession at King's College Hospital, London, and, after qualifying in 1925, held resident posts at his own

at the Royal Waterloo Hospital for Children, and at St. Andrew's, Dollis Hill. About four years ago he entered into partnership with Dr. E. B. Hinde of Norwich, and became medical officer of the 4th Norfolk Territorial Regiment. He was on his way by road to join this battalion in camp at Roedean, near Brighton, when about 10 p.m. on July 14th he was involved in a collision with another car. He was taken to the Horley Cottage Hospital, where he died two hours later without recovering consciousness. He was buried at Church Norton, near Selsey, the C.O. of his regiment providing a bearer party and bugler to accord him the last honours. Dick Yelf was 36 years old and unmarried. He was keen on his work and games. He played Rugby football for his school and hospital, and was devoted to swimming and music. Above all, he had a great faculty for friendship, and many contemporaries at school and hospital and in the regiment will miss his cheery personality.

Dr. ELIZABETH GOULD BELL, who died recently at her residence, College Gardens, Belfast, was one of the first women medical graduates in Ireland, taking her degrees in the Royal University, Ireland, in 1893. Dr. Bell devoted most of her time to the welfare of children and women. She was honorary physician to the Women's Maternity Home and the Babies' Home, Belfast, and one of the medical officers appointed by the Belfast Corporation in connexion with their babies' clubs welfare scheme. Ill-health compelled her to resign the latter position some years ago. She was one of the keenest advocates in the pre-war movement for the extension of the franchise to women, and through this she became a close friend of Mrs. Pankhurst and her daughter and Lady Betty Balfour. Dr. Bell married Dr. Hugh Fisher, who died some years later. There was one son of the marriage, Mr. Hugo Bell Fisher, who was a medical student at Queen's University when war broke out, and who died of wounds received when his battalion of the Munster Fusiliers was decimated at Passchendaele. His mother also volunteered for service in the campaign, and was in charge of a ward in the Malta Hospital.

The death took place on July 13th, in Dumfries and Galloway Royal Infirmary, of Dr. ROBERT GLOVER, a well-known surgeon in the Dumfries district. Dr. Glover, who was born in 1868 at Maxwelltown, took a medical course at Edinburgh University, and graduated M.B., Ch.B. there in 1907. After holding a resident appointment at Preston Royal Infirmary, and practising for a time at Manchester, he settled in Dumfries. Latterly, being in indifferent health, he gave up private practice to a large extent, and accepted the post of medical superintendent of Dumfries and Galloway Royal Infirmary. Dr. Glover has two brothers in the profession, Dr. T. A. Glover of Doncaster and Dr. J. A. Glover of Tadcaster.

Mr. JOHN FREDERICK JENNINGS, F.R.C.S., whose death we record, was born at Cardiff on August 7th, 1876, the son of John Jennings, a timber merchant. Educated at the Cardiff University, in Geneva, and privately, it was intended that he should enter the business of his father. He decided, however, that he was more suited for medicine than for a business career, and entered as a medical student at St. Bartholomew's Hospital. He took the M.R.C.S. in July, 1900, and was selected by the late Sir Henry Butlin to act as his house-surgeon. Sir Henry resigned in November, 1902, and the rest of Jennings' term of office was passed under William Bruce Clarke, who then became full surgeon. In 1903 Jennings was elected F.R.C.S., and was for a short time a demonstrator in the pathological laboratory at St. Bartholomew's Hospital, then under the control of Professor F. W. Andrewes. Jennings went into practice in Mayfair as soon as his term of office had expired, and quickly obtained a large circle of patients, who also became his friends. His sound knowledge of his profession, his absolutely fair tolerating his buoyant manner, his fluent knowledge of pharac, and his numerous good stories went far to ensure

this success. During the Great War he acted as surgeon specialist to the Queen Alexandra Military Hospital, and consulting physician to the Swedish Hospital and to the Michil Hospital at Queen's Gate. He married Gwendolin Thomas in 1906, who survives him, but without children. He died on July 5th at 11, John Street, Mayfair, and the funeral service took place at Golders Green, the service being taken by the Rev. Christopher Cheshire of Holy Trinity Church, Sloane Street. P.

Dr. FRANCIS EDWARD FORWARD died at Motttingham, London, S.E., on July 2nd, aged 67, after an illness of over eighteen months. He was born at Chard in Somerset in 1866, and was educated at Sherborne School. After studying medicine at St. Thomas's Hospital he qualified M.R.C.S., L.R.C.P. in 1889, and obtained the diploma of F.R.C.S.Eng. a year later. After serving as house-physician and ophthalmic house-surgeon at St. Thomas's he was appointed medical officer of the Holberton Hospital in Antigua, British West Indies, and held that position from 1891 until 1899, during which time he was made a justice of the peace and a member of the Legislative Council of the Leeward Islands, of which Antigua is the seat of government. He was then transferred to H.M. Home Department, and held various appointments under the Home Office until he retired in 1930. On his retirement he received the O.B.E. Dr. Forward leaves a widow and one son.

The Services

DEATHS IN THE SERVICES

Major-General George Bainbridge, Bombay Medical Service (ret.), died at Dawlish on July 6th, aged 89. He was born in August, 1844, the son of Frederick Bainbridge, surgeon, of Knaresborough, was educated at Leeds and at St. Mary's, and took the M.R.C.S. and L.R.C.P. diplomas and the L.S.A. in 1866; subsequently the M.R.C.P.Lond. and the M.D.Durh. in 1891. Entering the I.M.S. as assistant surgeon on April 1st, 1867, he became surgeon colonel on August 4th, 1896, and surgeon major-general on August 16th, 1897. His whole service was spent in the Bombay Presidency, and wholly in civil employ, except for the short period of a year after his promotion to administrative rank, when he held the post of deputy surgeon general of the Sind District. He held the civil surgeoncies, successively, of Dhulia and Satara, till, in 1878, he was appointed ophthalmic surgeon and professor of ophthalmic surgery in the Grant Medical College, Bombay. He always had a particular bent for ophthalmic work, and about 1888, when he was at Karachi, he was specially detailed to operate on the Meer of Hyderabad-Sind for double cataract. After sick leave in 1880, he was again appointed civil surgeon of Satara, and afterwards of Karachi, and held the latter post till his promotion. In August, 1897, he became surgeon general with the Government of Bombay, and held that appointment for five years, till his retirement on October 30th, 1902. During his tenure of office plague was at its height in Bombay; he did useful and responsible work as a member of the Plague Commission, and was the author of a *Report on Plague in Sind in 1896-7*. General Bainbridge had been a member of the British Medical Association for sixty-five years. He never allowed himself much relaxation from his duties, but as a young man he was extremely keen on big game shooting and riding, and had many fine trophies. After retirement he led a quiet, studious life. He was an omnivorous reader of books on science, politics, sport, and travel, and also current medical literature. He retained his health and memory almost to the end, and had a richly stored mind.

Colonel Jonas William Leake, C.M.G., late R.A.M.C., died at Belmont, Surrey, early in July, aged 60. He was born on August 8th, 1873, the son of the late Surgeon J. R. Leake of the 80th Foot, was educated at St. Edmund's College, and at Charing Cross Hospital, and took the M.R.C.S., L.R.C.P.Lond. in 1897, and the D.P.H. of the London Colleges in 1906. Entering the R.A.M.C. as lieutenant on January 28th, 1899, he became lieutenant-colonel in the long war promotion list of March 1st, 1915, and colonel on December 20th, 1923, retiring in 1926. He served throughout the South African War of 1899-1902, when he took part in the relief of Ladysmith, including the actions of Spion Kop, Vaal Krantz, Tugela Heights, Pieter's Hill,

and Laing's Nek, also in operations in Natal, the Orange River Colony, Cape Colony, and the Transvaal, and received the Queen's medal with six clasps and the King's medal with two clasps. In the war of 1914-18 he was mentioned in dispatches in the *London Gazette* of February 17th, 1915, and January 1st, 1916, and received the C.M.G. In 1890 he married Mabel Mary, daughter of Mr. W. Morgan, and had three daughters.

Surgeon Commander Reginald Lyon, R.N. (ret.), died suddenly at Dundee on July 10th, aged 44. He was the second son of the late Andrew Thomson Lyon of Glenogill, and was educated at Glasgow, where he graduated M.B., Ch.B. in 1915. After qualifying he entered the Navy, became surgeon lieutenant-commander on July 16th, 1921, and retired on reaching the rank of surgeon commander six years later. He served in the war of 1914-18, receiving the medal.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

This week the House of Commons discussed the Estimates for the Departments of Mines and Education, and also for Scottish administration, including the Department of Health. Progress was made with the Cattle Industry (Emergency Provisions) Resolution and Bill.

The House of Lords was in Committee on the Traffic Bill.

In the House of Lords, on July 12th, the Royal Assent was given to the Finance Act, the Adoption of Children (Workmen's Compensation) Act, the Prince of Wales's Hospital (Plymouth) Act, and to other measures.

On July 16th the Ministry of Health and Provisional Order Confirmation (South Middlesex and Richmond Joint Hospital District) Bill was read the third time by the House of Commons.

The Health and Housing Committee of Conservative members of Parliament, with Sir Francis Fremantle in the chair, heard addresses on July 18th on the plan of the Amulree Committee for establishing a National Housing Trust.

In the House of Lords, on July 17th, the Ministry of Health Provisional Order Confirmation (South Middlesex and Richmond Joint Hospital District) Bill was received from the House of Commons with an amendment, with which the Lords agreed.

The parliamentary recess is expected to begin about August 2nd.

Milk Debate in the House of Lords

The second reading of the Milk Bill was moved in the House of Lords by Earl DE LA WARR on July 12th; the Bill has already passed the House of Commons. Earl De La Warr said the Bill attempted to increase the production of milk in the United Kingdom. The first method of doing this was by cleaning up the herds from tuberculosis, and the provisions for this were contained in Clauses 9 and 10. The second method, a scheme of milk publicity, included spending £500,000 a year for the next two years largely on increasing the supply of milk in schools for school children. So that the Government and the farmers could co-operate in a campaign for cleaning up the herds from tuberculosis there was to be a grant of £750,000 from the Exchequer over four years. Attested herds would be those completely free from tuberculosis. It would be necessary for a producer to have two successful tests, with a six months' interval, to show the herd to be completely free. As soon as this was done, the producer could apply to the Ministry for an official test at the expense of the Government. If the latter was satisfactory he would be able to enter the scheme for attested herds, and would receive on his milk a premium probably amounting to 1d. a gallon. Discussions were in progress with the Certified and Grade "A" (T.T.) producers whether they should come into the scheme. Another grade of herds, the accredited herds, would be administered by the Milk Marketing Board. These would have to submit twice a year to full clinical examination, and their produce would

have to attain to the Grade "A" standard. There would be a premium of 1d. per gallon from the funds of the Milk Marketing Board. Clause 11 dealt with publicity for milk. It was not intended that much of the £500,000 should be spent on advertising; the Government would like to see the money spent on reducing the price of milk in schools. At present over 800,000 children were paying 1d. per day for a third of a pint. The Government had nearly completed a scheme whereby these children would obtain their milk for 1d. a day.

Lord MARLEY said that what the country suffered from was not over-production of milk but under-consumption. He asked whether the Government was going to use public money to secure an increased consumption of the rotten milk now being distributed or whether it would wait until the milk was really good before increasing its consumption by school children. Lord De La Warr had told the House that the milk was bad. Lord DE LA WARR replied that he had not said that. Lord MARLEY, continuing, said the facts about the quality of milk had been given by other peers, and had not been controverted. The report of the Committee on Cattle Diseases showed Great Britain had the highest percentage in the world of tuberculosis-infected herds, being at least 40 per cent. of cows in dairy herds compared with a percentage of 4 in the United States and approximately 12 in Canada. The Committee had said that neglect of adequate precautions against increase of the disease made it improbable that tuberculosis was diminishing in British herds. Lord Marley cited a speech by Lord Moynihan at the Mansion House to the effect that 59 per cent. of cases of glandular enlargement and 35 per cent. of bone and joint disease in England and Wales were due to the drinking of contaminated milk, and in Scotland the proportions were far worse. This was the milk which Lord De La Warr was now going to advertise to be increasingly consumed in this country. There was to be a campaign, towards which the Government would contribute £750,000, to ensure the proper inspection of tuberculous herds. Dr. Elliot had stated in the House of Commons that this campaign would take a long time. Lord Marley asked if Parliament could receive a report every six months of the progress of the scheme. He noted that the Bill also contained proposals to pay premiums for pure milk; this was a good preliminary measure. He had seen it carried into effect in a Midland dairying combine which had its centre in Birmingham. A premium was paid there for each gallon of milk that came up to a certain bacilli count test, and had more than a certain percentage of fat-content. The result was that the number of bacilli per cubic centimetre had been enormously reduced and the fat-content had improved. Lord Marley thought the only way Parliament could ensure pure milk for the nation was by preventing the sale of untested milk by retailers. He suggested that retailers should, meanwhile, be compelled to put up notices in their shops to say that they were selling untested milk which might very well be contaminated.

Medical Profession Criticized

Lord CRANWORTH said the medical profession urged on Parliament the duty of cleaning up the milk supply, and pointed to impurities which existed in a very small section of the milk produced. He criticized the profession because it did not also speak of the unclean production of milk over-seas—for instance, in Switzerland and Denmark—where cows went indoors in the early autumn and never came out again until the spring. Parliament had no help from the medical profession in drawing attention to the import of skimmed milk into the United Kingdom, although analysis showed that practically the whole value lay in the sugar in the condensed skimmed milk. That was the only form of milk many poor children ever received. The harm to those children by drinking condensed skimmed milk was greater than if they drank the dirtiest milk produced on any farm in this country. It was quite true that possibly 40 per cent. of cows in country were reactors. Probably 80 per cent. of cows in the city were reactors. Probably 80 per cent. of these cows were discovered by careful and regular examinations. The scheme now being considered for accredited herds was admirable, but a still more important recommendation of the Animal Diseases Committee was that all herds should be subject to periodical clinical examination. Accredited herds would consist at first of those which their owners were sure were clean at the start. If these owners possessed any

doubtful cows they would hand them over to neighbours before clinical examination. He asked the Government to consider what the expense of the scheme would be. The number of reactors in certain parts of the United States had been reduced in ten years by about 60 per cent. The cost of that was 150,000,000 dollars. He asked the Government also to consider the reliability of the test. The present method was a double intradermal test. Any peers who possessed herds knew from experience how unreliable these tests were at present, and how an animal would prove one day to be a reactor and a week later not to be one. He also asked the House to allow for the strides made by scientific knowledge. A book had just been published called *Spahlinger contra Tuberculosis*. This described the course of Spahlinger's experiments in Switzerland and Norfolk, which were successful. The Government of Northern Ireland held an inquiry, and on December 17th, 1932, published a report of an official demonstration in Belfast, which showed that 100 per cent. of the calves immunized by Spahlinger's vaccine had resisted an infection of tuberculosis which proved fatal to non-vaccinated calves in a few weeks. Medical men might have reasons to prove that what was stated in this book was not true, but it was full of names of the highest repute, and deserved the attention not only of the Minister of Agriculture but also of the Ministry of Health.

Necessity for Standardized Tuberculin

Viscount ASTOR said there was general agreement that some milk was unsatisfactory and even dangerous, but it was easy to over-emphasize the consequent danger to children. Of the cows reacting to the tuberculin test only 22 per cent. gave tuberculous milk, and of the human tuberculous population only 5 per cent. suffered from bovine tuberculosis. The deaths from non-pulmonary tuberculosis in 1911 were 14,600. Last year those deaths dropped to 5,400. That indicated a decided improvement in the quality of the milk available for children. If they were to get tubercle-free herds and increase the number of tubercle-free cows a reliable test was vital. They needed reliable tuberculin, and also veterinary surgeons qualified by experience to carry out this difficult and delicate test. The potency or strength of all tuberculin used must be adequate and the same. He cited a memorandum by the Tuberculin Committee of the Medical Research Council emphasizing the need for this, and the fact that all tuberculin on the market was not of equal potency. Confidence would not be established in the minds of the public or of the farmers without reliability in the tuberculin used. Either the Government should standardize tuberculin or, if that were impossible owing to administrative difficulties, it should restrict the use of tuberculin for licensed herds to specified brands of known and adequate potency. Lord De La Warr should consult his experts to learn whether more frequent testing than twice a year would be desirable, particularly when a cow was brought into the herd. Lord ROWALLAN said the standardization of tuberculin had been before the medical profession as a goal for many years, and he hoped Lord De La Warr would do something to ensure this. If any large scheme of free testing were introduced in the United Kingdom there would not be sufficient experienced veterinary officers to carry it out, results would be anomalous, and years would be required to overcome the ill effects. Referring to Spahlinger's experiments, Lord Rowallan asked if the presence of tuberculosis could be detected by the ordinary means after injection. The use of B.C.G. vaccine in inoculation in Great Britain had been discredited because, after inoculation, the animal became a permanent reactor to the tuberculin test. He was not sure whether Spahlinger's inoculation would not prevent the testing of the inoculated animal later by the tuberculin test. He challenged Lord Marley's statement that Scotland was backward in the cleanliness of its milk. He called attention to an experiment made not long ago in the West of Scotland to test raw as against pasteurized milk. Milk from non-reacting cows was divided, half being pasteurized and half given raw to calves. At the end of a year each of the calves which had been fed from sooty udders on pasteurized milk reacted to tuberculin, and a large number of those which had been fed on raw milk. Lord De La Warr said that at present the English certified Grade "A" milk producers were not under the Milk Board. It would be dangerous if they were left out of the scheme

adumbrated by the Bill, but new regulations might be disastrous just when this milk was required. An enormous amount of unestablished theory about tuberculosis ought to be scientifically checked before drastic alterations were made.

Replying to the debate, Lord De La WARR said that for the final test of herds only standardized tuberculin would be used. It was hoped that when future legislation made possible the control of certain therapeutic substances tuberculin would be one of the first substances to be dealt with. Milk sold in schools would be approved by the medical officer of health, and also by the school medical officer if he were not the same man. Lord Marley's charge that the Government was going to force dirty milk into the schools was made without inquiry into the facts. The milk from many areas and many farms could be improved, but it was unnecessary to libel the whole commodity as Lord Marley had done. Lord MARLEY said he had only contended that milk was a bad and dangerous drink unless produced in clean conditions from herds which were properly tuberculin-tested. Lord Moynihan had said he would rather put a barrel of gunpowder in his nursery than a glass of milk, but that was an exaggeration. Lord De La WARR, in conclusion, said this Bill was a first step. It might be desirable eventually to work out a scheme for supplying completely free milk to schools.

The Bill was read a second time without a division.

Restoration of Economy Cuts

Supplementary Estimates issued on July 12th include £1,700 to meet the extra cost of the restoration, from July 1st, 1934, of half the abatements made from the remuneration of part-time medical and dental referees and consultants under the Ministry of Health in 1931. The Ministry of Health Supplementary Estimate also includes provision of an appropriation-in-aid of £301,300. The restoration, from July 1st, 1934, of one-half the abatements from the remuneration of insurance doctors and chemists involves this reduction in the amount to be applied toward expenses of administration of national health insurance under the National Economy (National Health Insurance) Order, 1931. The similar appropriation-in-aid for the Department of Health for Scotland is £34,200. A new estimate of £1,556,500 for services under the Milk Bill, when passed, includes £6,500 for payments in the year ending March 31st, 1935, after consultation with the Minister of Health, for securing as far as practicable that the milk supplied for human consumption in England and Wales is pure and free from the infection of any disease. The similar Estimate for Scotland is £12,000.

Poor Relief in Scotland

The Poor Law (Scotland) Bill was read a second time by the House of Lords on July 12th. In moving it, Lord STRATHCONA AND MOUNT ROYAL said Clause 8 aimed at the break-up of the general or mixed poorhouse. Separate accommodation was desired for the sick, the children, and the aged and infirm. Clause 10 gave specific statutory authority for the boarding-out of children, which had long been a feature of Poor Law administration in Scotland. Clause 11 proposed to incorporate the provision of the National Health Insurance Act, 1924, disregarding the first 7s. 6d. of health insurance benefit when calculating the means of an applicant for poor relief. It was also proposed that the first 5s. of sick pay from a friendly society or trade union should be disregarded, as in England, and the first £1 of a wound or disability pension.

Tarring of Roads and Cancer

On July 16th Mr. SHAKESPEARE, replying to Mr. Hepworth, said that investigations into the theory that the tarring of roads was possibly connected with the existence of cancer were already being undertaken in various quarters, and any available information on the subject would receive careful consideration by the Departmental Committee on Cancer. The Minister of Health was advised, however, that prolonged inquiries would be necessary before any definite conclusions could be reached.

perpetuated this injustice on the motoring public they were in some danger of raising insurance premiums, especially on the lighter class of vehicles, to a point which many motorists could not afford to pay. The EARL OF PLYMOUTH said that the amendment was open to a number of objections, and he could not accept it. Lord SOMERLEYTON said that the hospitals were not built for motorists, but for the sick poor of the neighbourhood. The hospitals found great difficulty in getting payment for the treatment of road accidents, and the total cost to hospitals of such accidents was about £230,000 a year. That sum spread over 2,000,000 motorists would not mean more than about 2s. 6d. each. He would, however, withdraw the amendment at this stage.

The amendment was withdrawn.

(Further consideration of the Bill in committee was adjourned until July 19th.)

A Plea for More Nursery Schools

The House of Commons in committee, on July 17th, discussed the vote for the Board of Education, when Mr. F. WELSH advocated more nursery schools. He said that another 250 were required. They would cost £2,000,000 to build, but it would be a good investment. Miss RATHBONE expressed the view that the medical tests in the schools for malnutrition were not satisfactory. Mr. RAMSBOTHAM, in reply, said that Miss Rathbone would do much more good to the cause she had at heart if she would try to impress on all concerned a better understanding of the diet provided in the home.

Committee on Rehousing.—On July 9th Mr. SHAKESPEARE informed Mr. Chorlton that the Minister of Health had appointed a committee to advise on buildings required in rehousing after slum clearance. Sir George Humphreys would be chairman, and Mr. A. Zaiman, whose services had been lent by the Department of Scientific and Industrial Research, would be secretary of the committee.

Successor to Dame Janet Campbell.—Replying, on July 12th, to Mr. T. Smith regarding the post left vacant by the resignation of Dame Janet Campbell, Sir HILTON YOUNG stated he had placed in charge of the maternity and child welfare work a most experienced woman medical officer, who had previously acted as deputy to Dame Janet Campbell. She was directly responsible to the Chief Medical Officer, and received additional remuneration for her increased responsibilities. Another woman medical officer would shortly be added to the staff engaged on this important branch of the work of the medical staff. Replying to Sir Francis Fremantle, Sir Hilton Young said the title of the office was subject to an alteration, which he would explain if required.

Reports of School Medical Officers.—Mr. RAMSBOTHAM told Mr. Tom Smith, on July 12th, that the Board of Education had not recommended that the annual reports of school medical officers should be abridged as much as possible, but that repetitive matter should be abridged so as to enable fuller information to be given on new developments or special investigations.

Notes in Brief

The numbers of new houses completed and under construction under the Housing Act, 1930, at March 31st last were 17,569 and 10,512 respectively. The number of houses demolished under the same Act at the same date was 19,840.

To accelerate housing in Scotland the Secretary of State has appointed additional administrative and technical officers charged with the duty of visiting and assisting local authorities in preparing and carrying out housing schemes. Their headquarters will be the Department of Health, Edinburgh.

The Government's proposals for the encouragement of beef production in the United Kingdom include the establishment of a permanent Commission, an essential function of which will be to co-operate in a reform of slaughtering systems with a view to greater economy and efficiency.

Mr. Shakespeare states that in the five years ended last March nearly £262,000 was sanctioned for the purchase and lay-out of lands for recreation in rural areas, and much other land had been provided by gift or otherwise.

Medical News

A post-graduate course will be held at St. Thomas's Hospital from September 24th to 28th. The course includes lectures and demonstrations from 10 a.m. to 12.15 p.m.; ward rounds from 2 p.m. to 4 p.m.; and lectures from 4.30 p.m. to 5.30 p.m., each day. The fee for the course is £2 2s. The old students' dinner will be held at Dorchester Hotel on Friday, September 28th.

The next monthly clinical meeting for medical practitioners will be given at the Hospital for Epilepsy and Paralysis, Maida Vale, W.9, on Thursday, July 26th, at 3 o'clock, when Dr. Anthony Feiling will demonstrate. Tea will be provided, and those intending to be present are asked to send a card to the secretary beforehand.

A course in psychology for public school masters, matrons, and others concerned with residential students, will be held at the Institute of Medical Psychology, Malet Place, W.C.1, from August 1st to 11th. The special problems of young people of all ages up to 19 years will be discussed, and practical demonstrations given at a children's clinic. The scheme has been organized by the Child Guidance Council.

The Fellowship of Medicine (1, Wimpole Street, W.) has arranged lecture-demonstrations at 11, Chandos Street, W., on July 24th and 31st, at 2.30 p.m. Also demonstrations at the National Temperance Hospital on August 11th, and at St. George-in-the-East Hospital from August 13th to 17th. All courses, demonstrations, etc., arranged by the Fellowship are open only to members. Particulars are given week by week in our *Supplement*, in the *Diary of Post-Graduate Courses*.

A medical congress on cider and apples was recently held in Paris, when papers on their dietetic and therapeutic value were read by Professor Porin of the medical school of Rouen, Dr. Legrain and Professor Labbé of Paris, and Dr. Motet of Angers.

A congress on *B. coli* infections and other intestinal infections and intoxications will be held at Châtell Guyon on September 23rd and 24th, when Dr. Heitz-Boyer will discuss the entero-renal syndrome, and Drs. Brulé and Garbau the effect of intestinal affections on the liver. Further information can be obtained from Dr. T. Balme, Châtell Guyon.

The sixth Congress for Therapeutical Paedagogy will be held from July 26th to 28th at the University of Munich, when the principal subject for discussion will be therapeutic paedagogy in the service of public health, inheritance, and education, when the chief speakers will be Drs. Wettstein, Pfandner, and Luxemburger. Further information can be obtained from the secretary, Erwin Lesch, Vossstrasse 12/2, Munich.

The Lord President of the Council has appointed Mr. E. Barnard, D.S.O., M.A., to be director of food investigation in the Department of Scientific and Industrial Research, and Mr. F. Kidd, M.A., D.Sc., to be superintendent of the Low Temperature Research Station, Cambridge. Both these posts were previously held by the late Sir William Hardy. Mr. Barnard has been assistant director of food investigation since 1931. He joined the Department of Scientific and Industrial Research on entering the Civil Service in 1919. Dr. Kidd, who has been on the staff of the Low Temperature Research Station since its establishment in 1922, has been engaged on food investigation work under the department since 1918.

Professor W. S. Lazarus-Barlow, chairman of the Appeal Committee of the British Empire Cancer Campaign, in his report to the Grand Council at its meeting held at the House of Lords on July 9th, reported that the proceeds of the Empire Day appeal will probably exceed £60,000. Of this sum £5,330 was the result of the wireless appeal on Whit Sunday evening by Lord Moynton of Leeds, and the balance from flag days, house-to-house collections, and various other efforts held in aid of the campaign on Empire Day in approximately 1,400 centres.

A notice by the University of London appears in our advertisement columns this week inviting applications for the University Chairs of Medicine and Pathology, both tenable at St. Bartholomew's Hospital Medical College. The salary for the chair of medicine is £2,000 a year; and for the chair of pathology £1,200 a year, together with £500 as pathologist to the hospital. Applications should reach the Academic Registrar, University of London, S.W.7, by September 18th.

A memorandum on the collection and storage of rainwater for domestic water supplies (Memo. 183W, H.M. Stationery Office, 1d.) has been prepared by the Ministry of Health. Experience of the drought has again emphasized the serious neglect in many parts of the country, of any attempt to make prudent use of rainwater for this purpose, and has also indicated the desirability of spreading more information of necessary measures. With a comparatively small expenditure rainwater can be conserved so as to provide generally a sufficient reserve for domestic purposes, not only in areas where other sources of supply are not available, but in areas where there are such sources but the cost of rendering them available is very high.

The council of Epsom College, at its meeting on July 11th, awarded the vacant "France" pension of £30 a year, together with a bonus of £12 a year, to Dr. John Henry Chaldecott.

The issue of *Paris Médical* for June 16th is devoted to bone and joint surgery.

The issue for July 7th of the *Nederlandsch Tijdschrift voor Geneeskunde*, the organ of the Dutch Association for the Advancement of Medicine, contains a sympathetic obituary notice of the late Prince Consort of the Netherlands, who was president of the Dutch Red Cross Society for twenty-five years.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors of their articles published in the *British Medical Journal* communicate with the Financial Secretary, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Atology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Medisera Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshuegh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Treatment of Raynaud's Disease

Lieut.-Colonel L. B. WARD, late A.M.S. (Upper Colwyn Bay, North Wales), writes: I would feel very grateful if any of your readers could suggest further treatment for a case of Raynaud's disease beyond what is usually given in textbooks, which consists usually of warmth and galvanism.

Deafness After Opothary

"M. M. S." inquires whether there is any evidence that insulin or thyroid extract causes deafness, or at any rate diminishes the acuity of hearing.

House Flies

"B. W. L." in reply to "G. L." writes: As I have had an identical experience both in England and in Africa I may be able to suggest a cause and permanent lethal cure. I have lived in a country house with nearly as many windows as "C. L." mentions, and for twice as many years. One window has always been chosen as a promenade for flies of all sizes: in one corner of this window a large fly-catching spider has constructed a domicile. Hundreds of flies are constantly being killed by this spider. As flies attract other flies, this window is never cleaned, but some of the dead flies are constantly removed. This window keeps the flies away from the larder and the other windows, which are kept clean and unattractive to flies. My wife, who is a naturalist, would not have the large spider, or any of the accessory spiders, removed on any account. We do not find it necessary to wage chemical warfare as "G. L." has done; we leave Nature to take her course without undue interference. It is useless to take windows out of their frames, as "G. L." has done, in order to find the breeding places. Perhaps there are horses near his house. He must look for the breeding places in manure or refuse, and these probably will not be far away. By all means wage war with "flit," etc., on other places, but not on a window garrisoned by spiders. As far as I know the fly-catching spiders never do harm to food, but flies can convey the most pathogenic bacteria known to man. Probably "G. L." will find Nature's remedy far more efficacious than chemicals. I have always found spiders far more efficient at killing flies than pampered cats at killing mice.

Exercises for Lumbago

Dr. OLIVER HEATH (London) writes in reply to the inquiry by "W. H. T." (*Journal*, June 30th, p. 1195): The discussion "W. H. T." is trying to remember may be that published on fibrositis in the *Proceedings* of the Royal Society of Medicine (vol. xix, Parts 1 and 2 (joint discussions), p. 30), and reported in the *British Medical Journal* (1925, i, 509). In the first reference (p. 32) I described my treatment of one acute attack three days after a gumboil, and of a second acute attack two days after an overdose intravenous inoculation of *B. typhosus* vaccine. The treatment evolved from these personal experiences consisted in frequent slow bending forward as if to pick up an object from the ground, just so far as and no further than the point where pain commences, followed by slow recovery to the upright position. With each repetition of the bending the movement becomes easier and pain less. For twenty-four years now, since the first severe attack of fever, I have used this exercise successfully to ward off numerous threatened attacks of lumbago. An alternative, necessitating help of another, is massage applied scientifically on the same principle just to the point of causing pain.

Income Tax

Assessment of New House

"M. B." has had a new house built and moved into it on completion on March 24th, 1933. It has been assessed to income tax at £53 10s. net. When and for what periods will tax be payable?

* It is probable that the authorities will ignore the few days prior to April 5th, 1934, in which case tax will first become payable, as for the financial year 1934-5, on January 1st, 1935. Income tax on property is chargeable on the current year's basis.

Schedule A Assessment

"A. M. R." has a house of which the gross value for rating purposes is taken as £140, and the net rateable value as £113. What should be the corresponding Schedule A assessment?

* £140 gross, less the usual statutory allowance for repairs; if the gross Schedule A assessment were taken as £113 there would, in effect, be a double allowance for the cost of maintenance.

Assistant becoming Partner

"G. T." has been an assistant, and is going into partnership with his principal on July 1st, 1934. The practice has been assessed on the cash basis, and the change is not likely to affect materially the gross income of the practice. Should the practice be assessed as a continuing concern?

* Yes, undoubtedly—in that event the firm's liability for the whole of 1934-5 will be assessed on the net profits

of the practice for 1933, when "G. T." was a paid assistant and the profits reduced by payment of his salary and car allowance; obviously the division of an assessment so reduced between the two partners will benefit both. In addition, the same advantage will apply to June 30th, 1934, and therefore will affect half the assessment for 1935-6. This does not necessarily mean that the inspector of taxes will agree to the continuance of the cash basis, but we see no reason why he should object to that course. With regard to "G. T.'s" car depreciation claim, there is no need to have the car valued as at July 1st, 1934; the value as at that date can be calculated on a 20 per cent. written-down basis.

General Household Expenses

"J. S. T." states that in the town where he lives the usual professional allowance is one-third of the general household expenses, whereas in Edinburgh, so he is informed, the ratio is two-thirds. Is it worth while his appealing to the Commissioners?

* The higher ratio in the cases where two-thirds is given is probably due in part to the fact that high rents are paid for houses in a particular street or quarter—the ratio would obviously be higher in, say, Harley Street than in a small country town. In the latter case the remaining two-thirds of the rent might very well be only a fair equivalent for the private accommodation. We hesitate to advise an appeal to the Commissioners, though it might succeed, as such questions are often matters of general decision within the area for which they act.

LETTERS, NOTES, ETC.

Triplets Without Tears

Dr. GEOFFREY BARBER (Dunmow) writes: The subject of triplets is not infrequently evoked to cause laughter in the music-hall, but one would not imagine that it would actually keep the parturient mother in peals of mirth. Yet the following case combines the two unusual features of three live sons at one birth and childbirth regarded by the patient as an amusing event. On July 12th I went to the confinement of a primigravida 25 years old. Labour was four weeks early, the abdomen was about normal in size for full time, but very puzzling to diagnose on palpation. Examination per vaginam showed that there was first a foot and later a buttocks presentation. Strong pains began at 3 p.m. The patient was very cheerful, and encouraged the pains by pushing hard herself on the fundus, and exclaiming, "Come out of it, you little rascal!" At 7.55 p.m. her efforts were rewarded by the birth of a small male child, delivered easily as a breech with extended legs. There were no efforts at respiration until this was stimulated by a gentle stream of CO₂. The uterus remained much the same in size, and the mother would not believe the birth until shown the child, when she laughingly suggested the presence of a whole football team to follow. Renewed efforts on her part bore a second male child at 8.20, also a breech, and the only slightly diminished uterus now confirmed the presence of triplets. Her spirits rose even higher, and the nurse and I could not fail to join in her laughter when she abjured the third's delay with, "Come out of it, you little toad!" The patient's mother, who was waiting below, became so worried that she rushed up the stairs and burst into the room to know if she was losing her reason, and was only partly pacified at the unorthodoxy of the laughter. A third very feeble boy was born at 9.20, and at 9.35 the single placenta followed. It was oval, with three umbilical cords in a line about four inches apart. The patient then demanded a meal, and is making a very rapid recovery. The suggestion to name the triplets Tom, Dick, and Harry was eventually turned down in favour of Mark, Luke, and John. Mark and Luke flourish, but John was feeble from the first, and died twenty-four hours later. Their aggregate weight was little more than 11 lb., so that the ease of the labour was due to its being on the "instalment system."

Young's Rule

While the terms "Young's modulus" and "Young-Helmholtz theory" of colour vision are known to every student, the eponym "Young's rule" (for calculating the dosage of drugs suitable for children) is less familiar, and even those who are accustomed to its use may not necessarily associate it with Thomas Young. In the

current number of the *British Journal of Children's Diseases* (April-June), Dr. W. R. Bett quotes the original wording of the rule taken from Young's *Introduction of Medical Literature* (1813, p. 428). A brief account is given of the man, who is described as one of the most prodigious and baffling figures the world of science has ever seen. A precocious child, who before the age of 4 had read the Bible through twice and by the age of 14 knew a dozen languages, he became F.R.S. while still a medical student. As a doctor he was too scientific to become fashionable, and in his bedside manner he lacked the necessary air of assurance. The physician was eclipsed by the physicist, who was the author of the wave theory of light. As an Egyptologist he was a pioneer in deciphering hieroglyphics.

Anglo-American Continental Medical Society

A meeting of the Anglo-American Continental Medical Society and its friends in the British Medical Association will be held next week during the Bournemouth meeting. Members and guests will assemble at 12.30 p.m. on Friday, July 27th, and lunch together in the Pavilion. Those wishing to attend should communicate with Dr. Tom Williams before July 23rd, at the Royal Societies Club, St. James's Street, S.W.1.

Addendum

In the footnote to our review of Professor J. R. Blayney's *Dental Pharmacology and Therapeutics* (July 14th, p. 68) the name of the publisher—Henry Kimpton—was accidentally omitted.

Disclaimer

Dr. R. BLAIR GOULD (London, W.) writes: My attention has been drawn to an article concerning myself which appeared in two London daily newspapers last week. I wish to make it quite clear that this article was published without either my knowledge or consent.

"An Encyclopaedia of Sexual Knowledge"

Dr. NORMAN HAIRE (London, W.) writes: Anybody reading the report on page 94 of the *Journal* for July 11th of the prosecution concerning a pamphlet advertising the "Encyclopaedia of Sexual Knowledge," in which my name was mentioned, would be justified in inferring that I was responsible for the pamphlet. I should be obliged if you would publish this disclaimer. The facts are these. I was engaged to write some new chapters for the English edition of the book, which had already appeared in French, and to edit the English edition. Unfortunately I did not foresee that there would be any need for me to obtain an assurance that advertisements of the work should be subject to my approval. Ten thousand copies of the pamphlet were sent out before I ever saw it. As soon as I saw it I protested to the publisher that it was in bad taste, and that I objected to its being issued in connexion with a work under my editorship. I showed him copies of other pamphlets advertising books on sexual subjects issued by leading London publishers, and asked him to let me prepare a pamphlet along these lines to take the place of the one to which I objected. He refused to do so, and of course I had no way of compelling him. I had to be contented with his permission to ameliorate the pamphlet slightly, but my draft for the revised pamphlet, which I regarded as at any rate less objectionable than the original one, underwent alterations and was sent out without a proof being submitted to me. I protested again, and received an apology and an assurance that in future proofs of all new advertising matter would be sent to me. It was, however, too late for this to be of any use to me, and as a matter of fact the police authorities had already visited the firm's offices in connexion with the pamphlet. In your report the manager of the defendant company is stated to have said in court: "It was revised and extensively altered by the editor, Dr. Haire, before being sent out." If this is an accurate and full report of his statement it is the truth but not the whole truth, and conveys a false impression. As I was absent on an obstetric case in Scotland when the case was heard I was unfortunately not able to bring out these facts in court.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 44.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JULY 28th, 1934

British Medical Association

ONE HUNDRED AND SECOND ANNUAL MEETING, BOURNEMOUTH, 1934

President's Address

ON

CLIMATE AND HEALTH

BY

S. WATSON SMITH, M.D., F.R.C.P.Ed., M.R.C.P.Lond.

HONORARY PHYSICIAN, ROYAL VICTORIA AND WEST HANTS HOSPITAL, BOURNEMOUTH

My first words must be spoken to my colleagues, to give them my most humble and hearty thanks for the very great honour which they have this day shown me by bestowing on me, though unworthy, the highest dignity in their gift—that of President of the British Medical Association. My next pleasant duty is to offer a most cordial welcome to Bournemouth to all members and visitors in the name of the community, and more especially on behalf of your hosts, the members of the Bournemouth Division, and in the name of the whole body of medical men in this town and neighbourhood, and of the civic authorities of this county borough. All have helped unsparingly so that this meeting may prove as attractive and interesting as it will be illustrative of the liberal hospitality and eminence of Bournemouth; and for this whole-hearted and generous support I would, at the outset, voice the gratitude, not only of the Division, but of the Association.

We have in our midst colleagues from every part of these Islands, and delegates and visitors from all quarters of the British Empire, to whom, as to our distinguished guests from other countries, we would stretch forth the right hand of fellowship. Members of the great priesthood of Medicine, sons of Aesculapius, grandsons of Apollo, it is for us, hand in hand, strenuously to carry on the good work begun, built up, and strengthened, age by age, by our predecessors, who established a community of interests whereby life and work are dedicated to the art and science of Medicine and Surgery, the healing and relief of sick and suffering humanity ever being the first and constant aim of all followers of Galen and of Luke, the beloved physician. That this meeting may prove valuable in scientific discussion, and enjoyable by reason of the rest, change, and entertainment hereby afforded, and that each of you may return to his "lonely furrow," refreshed in body and mind, with a store of happy memories of old comradeship revived and new friendships made, is our most earnest wish.

Introductory Remarks

In 1891 (from July 28th to 31st), forty-three years ago, the fifty-ninth Annual Meeting was held in Bournemouth under the presidency of John Roberts Thomson, M.D.Ed., F.R.C.P., a Freeman of this county borough, whose eminent services to the Association are gratefully remembered. His name is indelibly impressed upon the

hospital and other benevolent institutions of this town, in which he wielded a great influence for good.

Nearly half a century has passed since then, but our minds are still occupied by questions akin to those raised by Dr. Roberts Thomson in his opening address, which he devoted to topics of local and general interest to the profession and to the State, bringing forward important health problems for public consideration. Although the awakening of the conscience of the State to a sense of its duties concerning the public health has, naturally, been gradual, if not slow, matters have now reached a stage when local authorities are in process of developing the national hospital scheme for providing for the sick and disabled of all classes. Such schemes, which have a national outlook, must, in the future, continue to take the direction of the prevention of disability and disease by compelling better living and working conditions and environment as well as that of their treatment and cure; and should first take into consideration the views and demands of the medical profession, the members of which, above all sections of the community, know the real needs of the health situation, whether local or national.

We know that now and in the future we can speak with no uncertain authority through the British Medical Association, which ought to be trusted to hold the scales fairly and impartially between the medical profession and the great public which it serves. In the century of its existence the ever-widening responsibility and the beneficent work of the Association stand in bold relief, an imperishable record, with the name of one illustrious member after another as milestones to mark the direction which the policy and work have taken. It is important now that we should continue, like the realists we are, to take the broad view as to the means of promoting the public health, and to see things actually as they are in an objective and scientific spirit as facts rather than as ideals. Accordingly, I propose to address you upon a subject which, always of interest to the profession, has become more so because it is capable of inclusion in the scheme of things as a practical, effective means of securing speedier recovery in many conditions of sickness, and of maintaining a higher general standard of health—namely, *Climate in its influence upon Health*.

This subject is as old as the art of medicine itself, having its origin in the dim, distant past, when the

practice of medicine was still in the hands of priests and religious orders. It has renewed importance, however, now that medical science can the better gauge the greater value of natural processes and environment in preventive and curative treatment. In talking of climate we shall not now define the term in the Johnsonian fashion as "a space upon the surface of the earth, measured from the equator to the polar circles"; or in the sense used by Sir Thomas Browne, when he wrote (1643) that he was born in the eighth climate; or again, in the popular meaning, as a region differing from another by reason of the temperature of the air. We shall define it in a broader sense, the meaning of the word, modified by time and necessity, indicating all the solar and terrestrial factors and influences which affect animal and vegetable life, including sunlight, atmospheric temperature, humidity and pressure, movement of the air, and prevailing winds—the factors which make our climate what it is; and, whilst including airs, also embracing waters and places. My remarks will also refer to the history of medical climatology and hydrology generally, and to the advisability of a more frequent use of British spas and health resorts.

In the choice of this subject it seemed to me that Bournemouth—fair as it is and so handsomely endowed by nature with beauty, grace, and charm—was a fitting place from which to speak. Alone of its kind and in the front rank of coastal health resorts, this area can claim to have restored health to invalids without number, and to have afforded rest and recreation for the many. Here, in Shakespeare's words, "The clymat's delicate, the ayre most sweet."

History of Medical Climatology

It is generally believed that, in the dawn of civilization, from the Middle East and from the shores of the Mediterranean, migrations of a people, mainly pastoral, took place in consequence of drought, a changed climate causing insufficient sustenance for tribes and flocks; and that thus knowledge spread eastward to China (2300 B.C.)—where even to-day a superstitious belief survives in the malign effects of climatic influences (Fung-Shui, literally wind and water)—to Libya and Egypt, whence to Greece, whither many Egyptian ideas made their way.

In Greece medical knowledge and practice flourished, chiefly in the Cnidos Peninsula and in Rhodes, the "rose-covered" island of the Aegean, where climate and physical influences seem to have been specially studied by the Greek philosophers; and in Cos and at Epidaurus, where the cult of Asklepios first appears. At these places health temples were founded—originally sacred shrines controlled by priests, their sites being chosen, not only from proximity to wells or hot springs, but also with a view to climatic salubrity. At these temples patients would drink the waters and bathe; the sick would flock thither to be treated by the presiding priests, just as cure and relief are now sought by pilgrimage to a holy well. The extent to which such "spas" were used is shown by the provision for entertainment at the health temple of Epidaurus of an open-air theatre capable of accommodating 12,000, and of a stadium for 20,000, spectators.

Pausanias, in his *Description of Greece*, mentions that whilst visiting Epidaurus he met a traveller from Sidon who declared his opinion that Apollo was the sunshine and Asklepios, his son, the fresh air. His worship as the god of healing was widely spread among the Greeks. His powers included even that of raising the dead. In his honour temples were built at many places, the most notable, that of Epidaurus, becoming the traditional seat of the cultus of the god, originally probably a form of sun-worship.

A salutary belief underlay the religion of Asklepios, that the maladies of the soul could be reached through the subtle gateways of the body; that, in the words of Walter Pater, "the body became but an handmaid of the soul." Thus the Greeks strove for perfect physical development, esteemed even above learning, their artists and philosophers employing their rare talents in the production of beauty and the search for truth. This idea of a select humanity was revealed in the Stoic plan of a world of the wise only, and in later Christian times found its expression in the conception of the Church as the only pathway to salvation for the human race.

The earliest surviving treatise on climatology is the chapter "Of Airs, Waters and Places" in the works of the immortal Hippocrates (460-370 B.C.), Father of Medicine, in which he deals with many questions of importance in public hygiene, giving numerous incidental references to the effects of weather and climate, winds, seasons, and localities. At this period Greek art and learning were at their zenith, instructing, edifying, and refining the world as they still ought to be doing. Hippocrates showed an extraordinary grasp of matters relating not only to climate and its causes, but also to the art of medicine; so much so that he founded a system of physic which embraced the results of actual observation in place of the superstitious and hypothesis till then obtaining, and dominated medical practice for many centuries.

In Rome, Scipio Africanus (died 129 B.C.) was one of the first to order the construction of baths. Later, in A.D. 21, thermae were opened by Vipsanius Agrippa, son-in-law of Augustus and grandfather of Caligula. It became customary to build a large bath over a natural hot spring, attaching to it several smaller baths. The neighbourhood of these became fashionable watering-places. Authors like Petronius and Martial throw much light on Roman bathing. The latter, taking note of the smaller details, describes a visit to the public and private bath each of which had its own regular customers. He watched the masseurs manipulating their patients, and a wily thief awaiting the right opportunity of pillaging from a bather's robe. It was usual for special bathing times to be allotted according to the rank and social status of the bather. Occasionally a bath would be used in common by the sexes; but such mixed bathing was forbidden by Trajan and by his successor Hadrian. In the reign of Justinian (A.D. 527-565), builder of St. Sophia, partitions were put up to separate the Byzantine sexes. During the Roman occupation of Britain spas and health resorts were founded, some of which, like Bath, "remain unto this day." London also had its medicinal wells and baths, the latter being early established there by the Romans.

In the obscure ages which succeeded the fall of the Western Empire the use of mineral springs dwindled, but after the Crusades (A.D. 1096-1272) warm baths again became fashionable, some associated with saints developing into centres of pilgrimage. During the fifteenth century the Greeks fled from fallen Constantinople, leaving the baths behind them for its conquerors, but taking with them into Italy their literature and learning, so that in the sixteenth century Hippocrates's work was again taken as an example to follow in the practice of medicine.

At length the immortal Harvey, by his work *De Motu Cordis* (1628), a record of investigation made by the experimental method, overturned the whole theory of the ancients, founding principles and the practice of physic on the scientific basis whereon they now stand. Thomas Sydenham (1675), Father of Clinical Medicine, "a rational man," laid great stress upon the seasonal variations of disease and the relation of disease-distribution to latitude.

At the end of the eighteenth and the beginning of the nineteenth century, the climatic dangers of travel were

demonstrated by the failure and destruction of the two expeditions into Africa of Mungo Park, himself a surgeon (see his *Travels*). But since the last few years of the nineteenth century a great improvement has taken place in tropical hygiene and sanitation. Many deadly climatic diseases are now known to be of parasitic origin, the constant warm climates of tropical regions rendering them the best breeding-ground for the organisms causing such diseases. Due to the direct effect of climate upon the parasites or their human or extra-human hosts, these diseases are fortunately absent from temperate and cold latitudes.

The second half of the nineteenth century was the scientific age, noted for its advances in medicine and surgery. Consequently, in the present century, many of the worst areas of the earth, where so many of our fellow-countrymen had been "climate-beaten" in the past, have been rendered wholesome and habitable for all races of mankind by pioneer work, done often under great risk to health and life, by colleagues of the profession. Such results have been brought about by the application of methods evolved by the original work of men like Patrick Manson, David Bruce, Ronald Ross, Andrew Balfour, and countless others, true pioneers of Empire, many of whom had passed on, forgotten by their own times, unhonoured and unsung; they constitute a splendid record of self-sacrificing labour on behalf of the civilization and well-being of mankind, and afford a demonstration of that spirit and genius, the proud heritage and hallmark of the profession of medicine.

In these days we seem to live in an age of transition, when each man's scientific knowledge and opportunities are expanding and increasing well-nigh beyond belief. Yet we find the same riddles presenting themselves for solution as in previous ages, merely changed in their scientific features. There must always be a demand for proof: a constant testing of our assumptions, investigations, and conclusions, to prove them true or false, and accordingly to receive or abandon them. The doctrines of science, many of which are now admittedly beyond dispute, at first confined to the scattered few, have been gradually gaining general acceptance. By the processes of trial and search for error they are constantly being clarified and corrected. Science, indeed, by its revelation of the established order of things, shares common ground with Religion.

Of Airs

"It is no wonder," wrote Clarendon (1647), "if England is generally thought secure, with the advantage of its own climate." There are those, indeed, who believe climate to be the most influential of the natural causes controlling the destinies of mankind. The observations of centuries on climate in its relation to the treatment of disease amply prove it to be one of the most valuable resources of the physician. The study of its phenomena, therefore—that is climatology—should have a corresponding value and importance.

Apart from secondary causes, biologically concerned, such as temperature, humidity, altitude, winds, soils, etc., the chief factor governing climate would seem to be insolation. The world-distribution of sunlight, and the resulting variations of temperature, appear to determine the differences between coastal, plain, and hill climates; as also such matters as diversity of colour types (the pale Eskimo, the fair-haired Scandinavian, the bronzed Arab, and the dusky negro of the Equator).

That, under Providence, the habitable globe depends for its existence on the sun, is a truism. The importance of sunlight to life and health cannot be over-estimated; indeed, it has become the fashion to assess the climatic value of a locality by the amount and intensity of the

ultra-violet light which it may receive in the course of the year. It is desirable, however, to impress upon the community that, whilst the sun is our greatest natural friend, he can, if regarded with disrespect or insolence (*ὕβρις*), become an equally potent foe. Here again it is the duty of the profession to counsel that moderation (the *σωφροσύνη*—*τὸ μὲν δὲν ἄγαν* of the Greeks) essential to the successful practice of any theory.

For an excessive exposure to light-rays, whether natural or artificial, not only entails fatigue and exhaustion, but also produces early degeneration of the skin, such as may be seen in sailors or in those who have lived for many years under tropical skies. The external ears, the lower half of the face, and the backs of the hands degenerate so as to exhibit a skin become thin, atrophied, and pigmented, upon which are grafted warty growths which, later, may assume a malignant form. Because of immediate and remote risks of over-radiation, caution should be advised in the use of the sun-bath and of artificial-light-baths. But, properly and prudently used, sunlight is of inestimable value. From the point of view of the man of business alone it has been proved that daylight and industrial efficiency are directly proportional, the one measuring the other. Such efficiency may also be encouraged by the creation of a so-called artificial climate, mechanically controlled as to temperature, humidity, and movement of air, promoting ventilation indoors, which should be applicable with advantage to the modern hospital or school, and to places of business or amusement.

But the sun is the ruler of all climates and determines temperature, the lessened or increased humidity of which has been used as a practical means of classifying climate as bracing and tonic, or sedative and relaxing; the former including busy places providing entertainment and excitement suitable for those needing bracing-up, an escape from routine-business, and change from sedentary work; the latter qualifying resorts favourable to rest and tranquillity, beneficial in nervous complaints, such as insomnia, in high blood pressure, or in disorders of the heart and circulation. There are, however, in the British Isles, all gradations between the two extremes. The term "relaxing," in reference to climate, I use in no derogatory sense such as enervating, but as synonymous with "sedative," indicating the quiet and repose desirable for the relief of these and other conditions of ill-health, and the maladies of old age, compelling a slowing-down of the pace, and encouraging restful days and nights, and a reduced metabolic rate.

The ignorance of the majority as to the climate, and so the health resort, best suited for them is notorious. A careful study of an invalid's general state of health and mental traits should be made before recommending the suitable place. Often a climate with frequent but moderate variations will prove beneficial, the more so if combined with a regular rhythm of rest, sleep, open-air exercise, and a properly supervised and dispensed diet; beautiful surroundings, changes of scene and of manner of life, all helping to encourage the invalid.

As our knowledge of applied climatology increases it will be found to be more and more of value as a factor in the successful treatment and diminution, or even elimination, of disease, the results of which, under differing climatic conditions in various parts of the world, and especially of the British Isles and Empire, will thus be tabulated and mapped out.

Of Waters

"To Epsom by eight o'clock," wrote Samuel Pepys, "to the well; where much company, and I drank the water: they did not, but I did drink four pints." From of old, the sick have benefited by medicinal water drinking

and bathing, the science of which was early to the fore in practical therapeutics. Interest in the subject has waxed and waned down the centuries, but, with widening knowledge of biochemistry, it should increase in importance.

Waters and baths are to be looked upon as factors accessory to climate, over which they may have a dominating therapeutic influence. Spas frequently specialize in the treatment of particular ailments, and should be classified not only according to type of climate but also upon their therapeutic indications. Mineral waters have their pharmacological action by virtue of their water-content, and of the various contained chemical and physical properties. Some have radio-activity, a property of high value, which is being increasingly utilized in treatment; a quality, however, so evanescent as to be speedily dissipated on exposure, so that such water must be used immediately when drawn.

Although from a medical standpoint doubt has been cast upon the value of the chemical properties of spa waters, this doubt has been dispelled with a more exact knowledge of biochemistry, which has led to a correct interpretation of their action, and so of their medical use. Up to the middle of the nineteenth century, when medical climatology again came into prominence, spa practice was purely empirical. Now every resort with a claim to therapeutic value should develop its own resources along scientific lines. For, in the words of Fortescue Fox, "Each spa has its own individuality," which should be fostered and guided aright by utility in treatment and by a reasonable limitation of its reputed curative value, so that a wise choice may be made by a physician for the benefit of his patient. A family resemblance among spas as to their medical value should not too lightly be taken for granted, for how often has it not been repeated that we do not treat diseases, but those who suffer from them; and so with spas as places of treatment, the aim of which should be to enhance and profit by the climatic and other advantages of the place. *Pars medicinae adjuvare non obstaré Naturam!*

Eliminatory Action of Spa Waters

Whatever the chemistry of medicinal waters their effects are several and complex. The eliminatory action, as carried out by Guelpa's abstinence-purgative and distoxicative method, described by him at the Annual Meeting in 1910, has proved of much value in certain autotoxic conditions needing alimentary rest and better excretion. Examples are to be found in over-alimentation and in any condition of auto-intoxication. The correction of faulty elimination and the "good-riddance" of waste products by starvation, coupled with the action of waters and baths upon the emunctories, is recognized as a chief method of treatment at all spas. It is of such proved value that it should not be lost sight of.

Replenary Action

There is another action of cardinal importance in health as well as in disease—namely, the replenary action; the regular replenishment of the circulation is a vital necessity, and the normal healthy intake of water should amount to three pints each day. Although volume of blood cannot yet be measured clinically, we know from observation that there is substantial variation in individual fluid capacity and tissue demand. Children of tender years, too young to help themselves, may, and often do, have so small a daily allowance as to suffer fluid starvation. In such we have seen a condition of collapse occur with empty surface vessels, distant, weak heart sounds, cyanosis, and sighing breathing, where quick recovery occurred with the filling up of vessels.

Similarly, the elderly may drink too little; but the fault of taking insufficient liquid during the twenty-four hours is more common among women, the resulting dehydration of tissue disposing them to calculous disease. Whereas dehydration, then, is harmful to the healthy, it has much direr consequences in illness.

Biochemical Action

This action of medicinal waters is perhaps of greater moment than hitherto generally believed. Calcium, iodine, bromine, iron, magnesia, salines, sulphur—all occur in readily assimilable form as a dilute solution of electrolyte in different spa waters, thereby providing a means of restoring to the individual what has been lost by dysfunction and disease; a replacement-therapy to stimulate chemical activity and repair tissue. Of these, the last-mentioned, sulphur, is perhaps less curative than has generally been thought; the very mention of it may be a reason for warning a particular case away from a favourite spa. It is often said that sulphur is valuable in skin diseases, but it is seldom found to be so in practice; in fact, it is harmful in some. Indeed, the only diseases where it is found useful are parasitic, or belong to the hydroa group; or, perhaps, are certain persisting dermatoses where a few applications are found of advantage in stimulating the eruption towards an effort at healing. But the prevalence of the parasitic class of diseases having much diminished with the discarding of the wig and with greater personal cleanliness, sulphur is much less in demand than formerly. In rheumatoid arthritis, however, being deficient in the liver, sulphur is found to be useful, exhibited in small doses.

Tonic Action

Spa waters, whether taken by the mouth or by bathing, have a tonic action; they stimulate the skin response to heat and cold, lessen heart load, improve peripheral blood circulation, and stabilize the heat-regulating mechanism, likewise improving general nervous tone, stimulating oxidization and general metabolism. The thermal action of all baths is exerted through the skin. Their effect upon the peripheral circulation and upon arterial tension is well known. The serious condition of so-called thermal debility is the real danger of bath treatment at spas, and is induced, especially in the delicate, sooner or later, by too frequent hot baths, as by hot climates. Thus the need arises for applying cold to the skin after hot baths to produce a reaction, which should, of course, be observed and encouraged. Particular disorders are recognized as especially amenable to bath treatment, if used in the early stages of disease, when as yet there is only functional derangement.

Of Places

When, a hundred years ago, England was still an agricultural country, holidays were few and short, and transport laborious. Since then the rural population to a large extent, much to be regretted, has migrated to the towns, where it requires cheap transport and changes of air and place to counteract intensive living, and to afford relaxation and rest away from the hurries of business and the trammels of social duties. In his *Anatomy of Melancholy* Robert Burton writes that "he that loves his health if his ability will give him leave must often shift places, and make choice of such as are wholesome, pleasant, and convenient . . . and generally for health to wander up and down." This is true enough to-day, when the restless spirit of the age must move about. The holiday rush to the sea is the tonic treatment for the masses, beginning at a time of year when health is at its lowest ebb after a winter's work.

Inufficient rest is a very fruitful source of premature collapse, so that a sedative environment has to be sought for escape from the nervous strain of modern life, such as can be found in the South Coast resorts, and on the plains, inland, away from valleys. There are many persons, however, with nervous system and cardiovascular and kidney disease, who do better in the familiar comfort of their own homes, in the cooler, bracing atmosphere of our temperate climate; but the milder climates inland or on the South Coast will bring relief to those suffering from conditions such as essential arterial hypertension, insomnia, or debility consequent upon the nervous strains and stresses of present-day life. The British Isles abound in bracing climates on the East and West Coasts and in the inland hills. The South Coast provides many sedative resorts where, to quote Cobbett, "there are as fine days as ever came out of the heavens."

In convalescence, his native place and air will often prove the most beneficial for a patient, because he is inured to them, *acclimatized*. Men are often misplaced, compelled to live unhappily in unsuitable environment, and so suffer accordingly; for survival can only come by adaptation to environment. Like disease, health is never static, but varies and differs in its manifestations from day to day, even from hour to hour. It takes a man, especially if of poor tissue and inferior physique, all his care to be able to maintain an efficient tissue-functioning during an average span of life.

With advancing age, when "the years draw nigh, when thou shalt say, I have no pleasure in them," it is wise to take an interest in Nature, whose simple ways thus acquire a charm for us hitherto, maybe, unnoticed, and the lovely villages and backwaters of the countryside "bring the soul nearer to the divine source of all being." The temperature and changeable climate of the British Isles have in the past bred a vigorous, hardy race, able to face life in almost any part of the world. This must be considered one of the chief underlying causes of the formation and successful growth of the British Empire, fostered and encouraged by the great Queen in the nineteenth century.

At the present time the fashionable rest cure appears to be the sea-cruise holiday in the sun, offering the complete rest possible for the healthy man, his whole mental outlook changing, as the waves carry him away for many days from shore conditions. For the healthy and vigorous nothing can be better; but for the invalid the discomforts of rough weather and sea-sickness, with the possibility of being "cabin'd, cribb'd, confined" in consequence, render such cruises of very questionable benefit.

Britain, being a most favoured land as to spas and health resorts, it is now generally understood in the profession that there is seldom, if ever, medical necessity to winter abroad, unless it be to obtain by altitude, or by dry or sea air, a suitable climate for the tuberculous or asthmatic. Moreover, the discomforts of travel, change of language and food, absence of home comforts and friends (to say nothing of the less satisfactory sanitary arrangements prevailing on the Continent), can be more easily faced, nay converted into sources of amusement, by the young, high-spirited, and healthy, than by the elderly or invalid.

On the other hand (and who, by the way, does not know the pleasure and excitement in the mere anticipation and planning of travel?), and in spite of Horace's famous dictum, *Caelum, non animus mutant, qui trans mare currunt*, there is no doubt that Continental or foreign travel, giving a complete change, may often be beneficial in cases of mental strain and nervous trouble; producing, as it does, a detachment from insular home prejudices, a broadening of outlook by unfamiliar scenes, manners,

and customs, and encouraging an interchange of visits and courtesies from country to country.

Concluding Remarks

Whilst the duty, too often neglected, of increasing the amenities and preserving the beauties of health resorts and spas must primarily belong to public authorities, the scientific, sane, and right guidance of their development should naturally be the part of an educated medical profession. Both locally and generally the whole subject ought to be surveyed, reviewed, and tabulated. Such places are a national asset; the increase of their value to the national health should therefore be the concern of the State and of public bodies to support and encourage. The medical men on the spot, with their experience and local knowledge, must inevitably be the advisers as to type of patient and disease to be benefited and relieved by the resources available at the place in question; and so should have it in their power to increase and improve the part played by our health resorts in the life of the nation.

Medicinal springs and baths should be under a public control, ensuring regular chemical analyses, purity, ease of access to the waters, and the circulation of accurate information available alike for rich and poor, for doctor or patient, detailing such accessory matters as climate, environment, endowment of the place with natural beauties, and its mental and bodily advantages: in a word, the individuality of the neighbourhood, *genius loci*. At these health resorts the public is demanding additional methods of treatment, including all manner of baths. Besides providing medicinal waters and baths, these resorts should offer a wide range of electrical, physical, and other external accessory means and methods for the re-education of body functions and of structures such as joints and muscles. So that an up-to-date watering-place, wishing to prosper, will do well not to be deficient in these respects or in available advice as to diet and mode of life best suited to the particular climate or malady.

The average hotel or boarding-house, no doubt, prefers catering for the healthy rather than for the sick. But the comfort and well-being of the latter are essential for the fair reputation or continued prosperity of any place calling itself a health resort, and could be fostered and maintained by a varied improvement of facilities for attendance and for the provision of various special diets. An admirable plan would include the provision in hotels catering for invalids of one or more State-registered nurses, responsible to the patient and his medical adviser, and to them only; an invalid annexe would be another device for the attraction and lodging of visitors not fitted for the ordinary daily routine of the healthy. Patients would be ambulatory or convalescent, not confined to bed or in need of any special medical attention.

There is much need for an increase at health resorts in the number of convalescent homes, suited to the means of all sections of the community, not excluding the overburdened upper and middle classes. Such institutions, municipally or privately owned, administered perhaps under health insurance schemes, might be, so to speak, territorial or regional, used near a patient's home in finer months, or in the south or west in winter. Their cost would amply be repaid by increased efficiency in work of all descriptions, and by gradual elimination of the later stages of such maladies as those of the rheumatic or fibro-itic type, which cause so much disablement with loss of time and wage. It is plain, then, that our health resorts are in need of necessary, but sympathetic, reorganization and improvement, much of which could be effected by a healthy rivalry in catering for the requirements of the jaded and sick, and by competition in the provision of the things that matter.

Among the things that matter vitally are those of the mind, far more neglected in England than on the Continent by poorer folk. We must not neglect and starve the mind, while lavishly catering for the body. Our ideal must be the *mens sana in corpore sano*; for the latter is virtually impossible without the former. Consequently our health resorts should be equipped for mental as well as for corporal benefit. The provision of libraries, art galleries, and museums is as necessary, if not so patently urgent, as that of convalescent homes and baths, for the ultimate attainment of our goal; for are not the former as much the sanatoria of the mind as the latter are those of the body? A day may well come when the healing art will include advice as to suitable studies in art, science, and literature as mental tonics.

The advantages of our health resorts are not infrequently lost to the sick through doubt, indifference, or

septicism as to their real value; by bad and selfish building development; by destruction of natural beauty; by ugly as opposed to reasonable and beautiful forms of advertisement; by too much noise; or by a cost of living which it should be the aim of all sensible government to reduce. Signs are not wanting, however, of good efforts to lay the foundations of a better state of things by a well-directed campaign of education as to the great advantages of British spas and resorts, not only to ourselves in these islands and to our kinsfolk abroad, but also to our neighbours on the continents of Europe and America.

Let us hope that the day will dawn when we shall be able in *propria persona* to recite the words of Alexander Pope in his *Essay on Man*:

"For me, health gushes from a thousand springs;
Seas roll to waft me, suns to light me rise;
My foot-stool Earth, my canopy the skies."

FOCAL INFECTION AS A PROBLEM FOR THE LARYNGOLOGIST*

BY

A. J. M. WRIGHT, M.B., F.R.C.S.

SURGEON, NOSE AND THROAT DEPARTMENT, BRISTOL GENERAL
HOSPITAL

I regard this subject as being peculiarly suitable for a discussion at such a meeting as this, in that our knowledge is at present fragmentary and in that such progress as has been made has been based rather on clinical observation than on laboratory research. I think it probable that you all have some sort of conception as to what you individually mean by focal infection, and I also imagine that these conceptions would differ one from the other. It would therefore seem necessary, since I have to open this discussion, for me to try and explain what picture is presented to me by this term. By "focal infection" I conceive the existence of a local inflammatory lesion or lesions producing pathological changes in organs or tissues of the body, such changes not being, as far as we can judge, due to the direct spread by continuity of the primary focal disease. I could perhaps clarify what I mean by giving a concrete example. Given a maxillary antral infection as the primary focus, I should regard a complicating conjunctivitis as being due to a direct spread of infection via the lachrymal apparatus, and therefore not as an example of focal infection. On the other hand, I should regard an iritis as being such a result.

In the great majority of cases we are unaware of the method by which the secondary changes are produced from a primary focal infection. In some cases, no doubt, there is a direct transfer of organisms via the blood stream from the primary focus, as is seen in the case of a gonococcal infection of a joint resulting from a primary lesion in the urethra. The clinical picture, however, in many cases seems to render it unlikely that this is the universal explanation, and we are therefore compelled to invoke the idea of the transfer of toxic products resulting from the activity of the organisms in the primary lesion. The picture of focal infection is further confused by the existence of infinite variations of sensitiveness to the effects of organisms or their products, such variations in sensitiveness being either inborn or acquired. I am aware that I have offered an imperfect definition, but the fact that our knowledge is at present imperfect adds enormously to the interest of the subject. As a result of a somewhat close clinical study extending now over many

years I am myself becoming more and more impressed by its importance, particularly in the sphere of chronic disease.

The Problem for the Laryngologist

In reviewing the possible sites for a focus of infection one finds that a considerable proportion of them occur in the domain of the laryngologist. The reasons for this are fairly evident. The skin is, as a whole, resistant to infections, and such infections, when present, do not tend to produce secondary results. The more usual site of infection is the lining of the food passages and upper air passages, and more particularly perhaps the aggregations of lymphoid tissues in these regions. When, therefore, we have taken our share, there is left for others, for practical purposes, the intestinal and genito-urinary tracts. The domain of the dental surgeon marches so closely with ours that, if we carry out our work with any degree of thoroughness, we must inevitably review his territory.

The problem for the laryngologist is, as I see it, twofold. He may, on the one hand, have to initiate the suggestion of a focus of infection in cases in which such an idea has not been thought of, and, on the other hand, when such an idea is put to him, he must try to decide whether such a focus is present and what degree of importance it assumes in the particular case.

It seems to me that this discussion can also be usefully employed in an interchange of our clinical experience as to how far, with our present knowledge, we can decide whether a focus of infection is present, and, secondly, as to how far the treatment of such a focus has resulted in improvement in the secondary lesions. It is along this path of clinical research that our knowledge, and therefore our practice, is likely to improve.

It would be well to consider, in turn, the various possible sites for the primary focus.

Nasal Infections

My experience has led me to join the school in which nasal infections, particularly those of the accessory sinuses, are only to be regarded as of constitutional importance when they are manifest—that is, when there is a definite infective lesion which can be recognized by routine methods of diagnosis. By this I do not mean to imply that there are not many cases of individuals who have a chronic infective focus, say in one antrum, but who do not appreciate the fact through having become so used to their symptoms that they regard them as the normal state of affairs.

Chronic antral infection, particularly if of dental origin, is the type of nasal sinus infection which most frequently

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

presents the picture of focal infection, the secondary results, as a rule, appearing as a chronic fibrositis or arthritis. In addition, changes in the nervous system do, I believe, sometimes result, and some cases of nerve deafness and optic nerve defects can be explained by such a focus. The type of chronic nasal pansinusitis accompanied by hypertrophic changes with polypi very rarely acts as an infective focus.

Dental Infections

The results produced are similar to those which I have just enumerated as following a chronic antral infection. In considering infection in the mouth, I believe that more importance is to be attached to one dead tooth with an apical infection than to widespread pyorrhoea, presumably owing to the fact that the former is a closed focus and therefore more prone to discharge its products into the blood stream.

Tonsillar Infections

These, you will agree, present the greatest problem of all. For some reason the faucial tonsils seem to be much more usually the seat of a focus of infection than either the nasopharyngeal or lingual tonsils. In addition, the picture of focal infection results from a primary tonsillar disease more often than from disease in any other site in the body. The tonsils seem to have a particularly intimate association with the general vascular and lymphatic systems, and it is, no doubt, their function to absorb samples of the infections in our environment, presumably with the object of establishing immunity. Under civilized conditions, in which opportunities for gross infection abound, such as in the modern cinema, this lymphoid protective machinery seems to break down and become chronically infected, and, by introducing products from such infection into the body to an excessive degree, to produce serious damage to the organism. As a result of a chronic focus in the faucial tonsils there can, I believe, be produced chronic lesions in the skin, joints, heart, kidneys, nervous system, and organs of special sense.

It is in diagnosis that the tonsils present their greatest problem. How can we decide when infection is present? Can the bacteriologist help us? Must we depend on the clinical history, which I believe to be of very great importance, as not infrequently a history of slight recurrent sore throats can be obtained? How far can examination of the tonsils themselves help? Is hyperaemia of the anterior faucial pillar a helpful sign? Is the presence of cheesy secretion in the crypts of any importance? And how far can compression of the tonsils or the application of suction to them help in diagnosis? An interchange of views on these points would, I think, be of considerable value.

The Ears

The picture presented by a chronic infection in the middle ear is, I believe, most commonly one of an individual showing the general signs of a chronic toxæmia, such as some degree of anaemia, lassitude, etc., but without, as a rule, the typical picture of definite secondary changes in the joints or other parts of the body.

Having thus briefly considered the possible foci of infection in the domain of the laryngologist, I should like to consider the other side of the picture from this point of view. Is there any lesion of the nose, throat, or ear which can be regarded as a secondary result of such an infection? We have, I believe, in some cases of nerve or perceptive deafness such an example. I am becoming increasingly convinced that some of these cases are to be explained as resulting from the toxic effects of a focus of infection. To illustrate this, I should like to quote an example: A male, aged 52, was first seen by

myself twenty-one years ago, and has been seen at odd intervals ever since. His hearing during the last ten years had gradually depreciated owing to a nerve defect. Some eighteen months ago I suggested that he should have his mouth, which was obviously infected, put in order. I did not see him again until recently, when, to my surprise, I found that his hearing had recovered to a degree which brought it back to what it had been some ten years previously. Apart from the removal of his infected teeth, I discovered no other possible factor which could have produced this improvement.

Some Difficulties and Mistakes

As a final contribution to this discussion I should like to relate some of the difficulties and mistakes which are likely to be experienced in applying the principle of focal infection to practice.

1. *The Primary Focus may be Difficult to Detect.*—This state of affairs is most often met with in connexion with a tonsillar focus. As an example of such a case in which serious secondary results have followed a barely discoverable infective focus, I cannot do better than quote the following. A woman, aged 32, had suffered for some months from a pustular eruption on the face. When first seen over two years ago she gave a history of progressive oedema of a few weeks' standing, the urine being solid with albumin. Careful investigation of the medical history disclosed nothing beyond a vague history of occasional sore throats, in no case sufficiently severe to lay the patient up. Superficial examination of the pharynx revealed nothing abnormal, but retraction of the anterior pillars disclosed small and somewhat unpleasant-looking tonsils. Removal of these has resulted in complete resolution of both the nephritis and the dermatitis.

2. *A Mistaken Focus.*—In view of what has just been said it is not surprising that difficulty often occurs in deciding which of two or more possible foci is the guilty one. For instance, I regard the following case as an example of such a mistake of my own. The patient, a man aged 27, had suffered from recurrent attacks of iritis for three years. Two years ago I operated on his nasal septum, on the mistaken assumption that the iritis was secondary to a nasal infection. Six months later he developed a quinsy, which was immediately followed by an attack of iritis, and after this there was a succession of sore throats, followed on each occasion by a flare-up in the eyes. His tonsils were removed nearly a year ago, and, following this, the attacks of iritis have ceased and his general condition has enormously improved. In this case I have no doubt that the tonsillar infection was the primary one. As a result of experience I am now of the opinion that where one is in doubt as to the relative blame of possible foci in the nose and throat the tonsils are by far the most frequently blameworthy.

3. *Consecutive Foci.*—A misleading difficulty that not infrequently arises is that, following the surgical removal of an infective focus with resolution of the secondary results, at a later date a recurrence of these secondary lesions takes place, due, apparently, to the arising of a fresh primary focus in a new situation. Thus I believe we not uncommonly see an intestinal focal infection following on a tonsillar one, and, as in the case which I give here, a tonsillar infection following on a nasal one. In either case we have a descending infection, but it would be of interest to devote special attention to the question as to whether the reverse can take place—that is, a nasal infection follow a tonsillar one.

As an example of this occurrence of consecutive foci a female, aged 44, was seen five years ago with a history of nasal discharge of some years' standing, associated recently with severe muscular rheumatism. Drainage of infected nasal sinuses caused a complete clearing up of the rheumatism,

with considerable improvement in the general condition. Four years later, however, she had an attack of acute tonsillitis, which was followed by a recurrence of the rheumatism. Removal of her tonsils has resulted in improvement in her general condition and rheumatic symptoms.

4. Multiple Foci.—The occurrence of multiple infective foci presents a somewhat similar difficulty. Having discovered one focus, the surgeon is apt to rest content and thereby miss another, and possibly more responsible, one. An excellent example of this mistake can be shown by the case of a woman, aged 42, who, fifteen years ago, was affected with septic arthritis of relatively sudden onset. This was presumed to be associated with infected teeth, and these were dealt with, with perhaps some degree of improvement, but the patient remained more or less an invalid. The occurrence of an otitis media two years ago led, as a routine, to the examination of the nose. To my surprise I found on transillumination that the antrum on one side was completely opaque. Operation disclosed chronic disease in the antrum, which from its nature had almost certainly resulted from the original dental infection many years previously. A recent note of her condition states that she is now fit. Some deformity of the joints remains, but there is no sign of any active disease.

To sum up, I hope that to-day's discussion may do something towards the consolidation of our ideas as to the scope of focal infection and as to the way in which the difficulties of its application to clinical practice may be surmounted.

ELECTROTHERAPY IN THE TREATMENT OF DISEASES OF THE GENITO- URINARY SYSTEM*

BY

W. J. TURRELL, M.D.

ELECTROTHERAPEUTIC PHYSICIAN, RADCLIFFE INFIRMARY, OXFORD

Owing to the fundamental character of its action electricity, in one of its many forms, has proved itself of value in a very large number of diseased conditions. If, however, as Dr. Golding Bird¹ wrote in 1847, when dealing with electrotherapy, we wish to act as "scientific and philosophic physicians," we must inquire into the "rationale of the process" which we employ. It is not sufficient merely to enumerate the various diseases which may be beneficially treated by electricity, or to allege a number of cures. There will be no advance in our methods, and none of our scientific brethren will be convinced, if we lay down an empirical classification of our remedies, baldly stating that "zinc ionization" is good for endometritis, or that diathermy is indicated for the relief of dysmenorrhoea. Such mere assertions will carry no conviction.

On the other hand, if we expound the "rationale of the process" which we employ—namely, that the septic membrane in endometritis can be thoroughly and completely destroyed by the electro-chemical process which ensues from the electro-deposition of a caustic-forming ion, such as zinc, upon the interior of the uterus—we afford an explanation of the "rationale" of our method—which is deserving of the consideration of all open-minded physicians. Or, if we point out how the relaxation of spasm and tension in dysmenorrhoea can be effected by the deep heat generated by the diathermic current, and how the vibratory process, which is the precursor and

generator of this thermal action, further serves by its dispersive action to relieve tension and pressure, then we may obtain a rational appreciation of electrotherapy from all except those whose complete ignorance of electrical methods is only equalled by their reluctance to learn anything about them. It is on such broad principles that I propose to open this discussion.

The main forms of electrical current employed in electrotherapy are: (1) the constant or galvanic current; (2) the interrupted currents of low frequency; and (3) the interrupted currents of high frequency.

Local Application of the Constant Current

In its general application the constant current owes its main effects to the reflex action induced by the stimulation of the skin nerve endings by the electro-deposition of various ions. In this form it is not of great importance to the subject of the present discussion. In its local or polar application, on the other hand, it is one of the most valuable remedies at our disposal. In the treatment of endometritis by the constant current we introduce a zinc rod or uterine sound within the uterus, and connect it with the positive pole of the source of supply. The zinc cations proceeding from this zinc rod carry the positive charge down to the mucous membrane of the uterus, at which point, owing to a change of liquid, another set of ions, mainly the hydrogen ions of the tissues and blood, continues the convection. The mucous membrane thus forms a virtual pole at which the zinc ion, yielding up its positive charge, forms with the oxygen and chlorine of the tissues an oxychloride of zinc, and, by the chemical decomposition involved in the formation of this salt and by its subsequent caustic action, the membrane is thoroughly and intimately destroyed. Provided the different electrode and pad surrounds the whole circumference of the abdomen, the destruction takes place over the whole inner surface of the uterus, and so evenly is the destructive process distributed that the destroyed membrane may be subsequently passed as a complete cast of the interior of the uterus.

The application lasts for about fifteen or twenty minutes towards the end of which uterine contractions, appreciated as pain, may be excited; these are an indication to cease the treatment. If the application causes any pain in its early stages it is evidence of complications in the appendages, such as pyosalpinx, and further treatment should be discontinued, since these cases are unsuitable for this method. It is interesting to recall that Apostoli employed the method to ascertain the condition of the uterine appendages. According to him, if the large current of 100 to 150 mA was tolerated the appendages were above suspicion. If a current of 50 mA excited pain the appendages were open to suspicion. Intolerance of 30 mA indicated serious trouble in the tubes, and if there was intolerance of 20 mA the uterine annexes should be removed.

From what, in current parlance, may be termed a fifty-fifty experience of curetting and zinc electro-deposition, I have no hesitation in pronouncing in favour of the latter method, except in cases from which placenta remains have to be removed or scrapings obtained for pathological examination. Zinc electro-deposition entails little inconvenience, and no nursing home, anaesthetic, or lying up. The apparatus required is of the simplest kind, the best battery for the purpose, complete with water resistance costing less than 5s. There is no better, no less expensive, and no more convincing method with which the general practitioner can begin electrotherapy. A similar method of treating gonorrhoea by zinc electro-deposition was introduced by Bouchet in 1907. He employed a zinc wire within a perforated rubber catheter, through which a solution of 1 or 2 per cent. solution of zinc sulphate

* Read in opening a discussion in the Section of Radiology and Electrotherapeutics at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

was irrigated. A similar method has been used with success for the treatment of otitis media, and many other conditions.

The history of electrotherapy shows us that one of the many and great disadvantages attending the lack of any systematic teaching of our science, and consequent upon its non-inclusion in the schedules of the examining boards, is that older and more valuable methods are often lost sight of owing to the glamour that accompanies the introduction of a hitherto unknown method of treatment. There is no doubt that the benefits of electro-deposition do not to-day receive the recognition they deserve.

Interrupted Currents of Low Frequency

While these currents are certainly among the most valuable and the most frequently indicated in other diseased conditions, they are of relatively little use in the treatment of genito-urinary disease. The method of the graduated electrical excitation of muscle by the faradic coil, which we owe to Sir Morton Smart and Mr. Rowley Bristow, is of great value in the restoration of tone to the abdominal muscles, and so indirectly aids in the relief of uterine malposition. The faradic coil is also of considerable benefit in the treatment of many cases of incontinence of urine in the male, and to a less extent in the female.

The Morton wave current, a unidirectional, interrupted current of low frequency, is often indicated in the treatment of the prostate, but I need say little in reference to this, since it will be dealt with fully by Dr. Howard Humphris, who has had far more experience in this than I have; it was, indeed, to Dr. Humphris that I owed my first introduction to this valuable instrument, the static machine. The very high voltage obtainable from this instrument—about 60,000 volts—and the very abrupt break of the current by spark discharge, yields a density of current which most thoroughly pervades the muscle or organ treated, and excites more powerful muscular contractions with less discomfort than any other method. Compare for a moment the effect obtained in this way, in the treatment of the prostate, with digital pressure on that organ per rectum. For cleanliness, convenience, and, above all, for efficiency, it must be evident that a method which enables us to produce alternate contraction and relaxation of the whole gland must be incomparably preferable to the remote kneading of its posterior surface by digital pressure. Among the most convincing proofs of the efficiency of this technique are the permanent cures which result from the treatment of those painful conditions of prostatitis which often follow old-standing cases of gonorrhoea.

Interrupted Currents of High Frequency

The interrupted currents of high frequency are a very valuable group in the treatment of diseases of the genito-urinary system. The paramount question in relation to the therapeutic action of these currents is whether their effects are due to heat alone, or whether they are, in part at least, due to the vibratory or oscillating action of the ions which precedes and produces this heat. I ventured to raise this point eleven years ago at the Portsmouth meeting in 1923, and the view then expressed was that this question should not be raised, as medical men were just beginning to appreciate the beneficial effects of diathermic heat, and their minds should not be confused by the possibility of these currents possessing any additional action. It is clear that this question cannot be dismissed in this summary fashion. On purely *a priori* grounds it would appear evident that a current of the high voltage employed, oscillating at a frequency of 1,000,000 to 30,000,000 times a second, must produce

effects other than the heat generated by the ionic collision at such a frequency and voltage.

Arguing from analogy, we recognize that the vibration of modern motor traffic is injurious to our old buildings. In this case it is not merely the weight of the vehicles that is the cause of the trouble, for we have had the slow-moving, but very heavy, traction engines for years past without any serious vibration damage resulting. The modern damage has resulted from a certain ratio between speed and weight, analogous to frequency and voltage. And it is possibly from the fast travelling and heavy motor buses that much of the damage has resulted. Passing from the coarser to the finer vibrations, we have the molecular disintegration, occasioned by the electromagnetic stresses, which takes place in the wire winding of our Oudin resonators—that is to say, if such resonators are wound with brass instead of phosphor bronze wire, the brass wire becomes so disintegrated in its structure, and so soft and friable, that a length of about six inches, when held horizontally, has insufficient cohesion of structure to support its own weight.

In the experiments of Wood and Loumis on supersonic waves of high frequency and high voltage, generated by a piezo-electric generator of quartz, we find a very striking example of the extraordinarily powerful "pounding" action of these supersonic vibrations. The voltage employed in these experiments was very high—50,000 volts—and the oscillations were 300,000 per second. In general outline the generator was of the triode valve type. Blood blisters, persisting for several weeks, were formed by the pounding transverse vibrations on the fingers holding a glass rod, the end of which was dipped in the transformer oil in which the vibrations were occurring. Small fish and frogs were quickly killed. "Filaments of living spirogyra were torn to pieces and the cells ruptured." Blood corpuscles were broken up by the molecular oscillations set in motion by these pounding vibrations.

D'Arsonval and Charrin found that the toxicity of a very active diphtheria toxin was destroyed by exposure to high frequency for fifteen minutes, although the temperature of the media or their contents never exceeded 98.5° F. Clinically, when administering diathermy, I have noticed the disappearance of a bruise exactly corresponding in its limits of disappearance to the area of the electrode. If this disappearance of the ecchymosis was due to heat the limits of its disappearance would be more diffused. The rapid subsidence of swelling in the treatment by diathermy of a recent injury, such as a Colles's fracture or a sprained ankle, is more rapid than can be accounted for as the effect of heat alone. It has been alleged that these disappearances of ecchymosis and swelling are due to the pressure exercised by the bandages which secure the electrodes in place, but I have noticed a similar disappearance, both of swelling and of ecchymosis, when treating a sprained ankle by a 30-metre wave-length. In this case the electrodes were not bandaged on but merely supported in position by lateral sandbags, and were only in contact with the ankle at the malleoli; the disappearances corresponded exactly in their limits with the high-frequency electro-magnetic field.

Bordier obtained very similar results to those of Wood and Loumis, although he utilized a frequency of 30,000,000 at a far lower voltage than they did. Thus there would seem to be an optimum wave-length of very high frequency at which these disruptive and dispersive results can be obtained. Now this is a point of great importance and interest when dealing with the short and ultra-short wave-lengths which are now beginning to excite so much attention. It would appear, I think, that there is not a specific wave-length at which any particular micro-organism can be destroyed, but rather an optimum

wave-length at which the organism can be destroyed at a minimum voltage, though at a longer wave-length an increased voltage would produce a similar effect.

Some fifteen or twenty years ago I was one of the first to treat dysmenorrhoea by diathermy. I was led to do so by the remark of a patient whom I was treating by diathermy for pelvic pain, unassociated with the menstrual period, to the effect that after her last period she had had the first period free from pain for fifteen years. I adopted this useful hint, and have learned the great value of this treatment in suitable cases of spasmodic dysmenorrhoea. It is, indeed, easy to visualize that the spasm tends to be relieved by the thermal effects of the high-frequency currents, and that dispersal of the engorgement is aided by the vibrations; the value of these united actions in the treatment of such distressing conditions is thus readily appreciated. I believe that the short or ultra-short wave high-frequency currents will prove to be of special value in these cases. Space will not allow me to deal fully with their advantages, but it must be evident that a technique which does not necessitate the removal of any clothing is in itself a great advance. This, however, is only a matter of convenience, and the specific value of the short-wave currents will be found to be due perhaps to some extent to their more rapid and finer vibrations, but chiefly to their more even concentration and action within the body. The long-wave diathermy of about 300 metres enters the body mainly by conduction, partly by condenser or leaky condenser effect through the skin, and in a few types of application by a condenser field action. Consequently, with such wave-lengths, the conductivity of the tissues influences to some extent the effect of the treatment. The short waves, on the other hand, excite their effects solely by a condenser field action; no current actually passing through the skin, the oscillations are excited solely within the body, and as a result the tissues and structures of the body react more evenly and uniformly. It is upon such lines that I venture to open this discussion and to explain the rationale of our processes; in this manner we travel along a path, parallel to that along which physical science is to-day advancing, towards a goal of as great efficiency and exactitude as has as yet been reached by any branch of medical science.

REFERENCE

¹ Golding Bird: *Lectures on Electricity and Galvanism*, 1849.

Census of England and Wales, 1931: Occupation Tables is now on sale at H.M. Stationery Office, price 30s. net. In addition to the statistics for the country as a whole, data are furnished in similar detail of occupational subdivision for twelve geographical regions into which England and Wales has been divided, and also for counties and large urban areas. For the smaller urban areas and for rural districts data are supplied according to a condensed list of occupations and occupational groups. The statistics relating to industries will be published in a separate volume. The principle upon which the classification is based is the nature of the work performed, though in the case of the productive occupations the nature of the material worked in has been embodied in the scheme as a factor essentially determining the character of the operations. Full details of the classification, together with an alphabetical index of about 35,000 occupational terms, is published in a separate volume entitled *Classification of Occupations*, price 12s. net. On this occasion for the first time statistics of persons out of work at the date of the census are included. The classifications of such persons embrace all classes of the community, including those outside as well as those within the scope of existing statutory insurance schemes.

NON-SPECIFIC COLITIS IN RELATION TO DEFICIENCY DISORDERS AND ANAEMIA

BY

D. C. HARE, M.D., M.R.C.P.
PHYSICIAN TO THE ROYAL FREE HOSPITAL

Colitis is here used as a general term for a well-recognized clinical condition; "haemorrhagic colitis" and "ulcerative colitis" are considered as synonymous terms. Colitis is a sporadic disease occurring with some frequency in England and other temperate climates. The cause of this disease has always been very puzzling, for no specific infection has been found, though its chief symptom—diarrhoea with blood and mucus—suggests a relation to the dysenteric infections. Notwithstanding the failure to establish a definite intestinal infection, treatment has been to a great extent concentrated on the local condition, and colon lavage is employed almost universally, often assisted by irrigation from above through a stoma in appendix or caecum. The unreliable results of such treatment and its failure to prevent relapse are, however, generally acknowledged.

The purpose of this paper is to point out the resemblances of this disease to a deficiency disorder, and to urge treatment with high vitamin diets and, in particular, the vigorous treatment of the anaemia, when present, as a cure of this may be accompanied by an amelioration or remission of the colitis symptoms. Emphasis is laid on the necessity for massive doses of iron or liver. The temporary increase in diarrhoea or of other symptoms which often follows at the outset is no contraindication to continuing the treatment. Improvement in the bowel symptoms may be slow, especially at the beginning of an acute relapse, and perseverance is required. It is urged that all local treatment and sigmoidoscopic examination should be avoided if possible, as the bowel wall is highly susceptible to trauma; examples of the harm that may result are given. If colon lavage is continued, it may keep up the diarrhoea and bleeding, and cause apparent failure of other treatments.

Colitis a Deficiency Disorder

The evidence in favour of adding colitis to the list of deficiency disorders of the gastro-intestinal tract is gathered from experimental and clinical sources. The study of experimental vitamin deficiencies shows that both vitamin A and the vitamin B complex are necessary for the development of the healthy mucous membrane of the intestine and for maintaining its resistance to infection (Cramer,¹ Goldblatt and Benischek²). McCarrison,³ and Tilden and Miller,⁴ working with monkeys, found intense changes in the colon with vitamin-deficient diets, and in these animals the clinical signs of human colitis were closely reproduced. In human beings it is recognized that good nutrition may completely prevent the development of clinical dysentery, even though the amoeba is present in the gut. It is not suggested that non-specific colitis is the outcome of a gross diet deficiency in the majority of cases in this country; it may be due to a latent deficiency which is either inborn or acquired as the result of diet and disease. Colitis resembles a deficiency disease in that it occurs in attacks, with spontaneous remissions and relapses which follow without apparent cause; the first attacks are often slight and transitory, and each relapse tends to be more severe than the last. The highest incidence of the disease is in the second, third, and fourth decades.

A consideration of the functions of the colon is of interest. Starling states that its chief value in carnivora

and man is as an excretory organ. It has a remarkably selective capacity with regard to drugs, being particularly concerned with the excretion of calcium, iron, and bismuth. The association of a severe iron-deficiency anaemia with colitis and with malignant growths of the caecum and ascending colon is of particular significance in this connexion. The special tendency of certain metabolic toxins, as in uraemia, to cause colitis may be due to their elimination by this route, and it seems probable that clinical colitis represents some toxic attack on a colon of low resistance.

The Characteristics of Colitis

The disorder affects not only the mucosa of the bowel but the muscle wall as well. There are hypertonicity and irritability of the bowel and areas of irregular spasm and dilatation, or a general contraction with loss of haustrations: this disturbance of tone is very persistent, and causes diarrhoea with colicky pains or spastic constipation, the symptoms often alternating in chronic cases. This high tone is found after all other symptoms have disappeared, and is evidence of the continued tendency to relapse (Larimore²). In acute attacks the colon wall becomes atrophied to a papery thinness, and may perforate; in long-standing cases inflammatory reaction and thickening appear. The mucous membrane is granular, velvety, and intensely injected, bleeding everywhere on light touch; superficial necrosis with sloughing and ulceration may follow. The maximum incidence is usually in the sigmoid colon, from where it spreads upwards and downwards; but the caecum may be severely affected or the whole colon involved simultaneously. The stools differ with the acuteness of the condition. In early, slight, or chronic cases they may be well formed, with adherent streaks of blood and little mucus: in the acute condition offensive liquid faeces are passed with varying amounts of mucus and blood, which are less intimately mixed than in dysenteric stools; pus is usually present microscopically. The appearance of stools passed in succession may be very diverse: this is an observation of diagnostic importance.

In a severe attack, or in a chronic condition, an anaemia of secondary type develops which may be out of all proportion to the degree of haemorrhage, and is found in non-haemorrhagic cases. Severe general oedema and fever sometimes accompany the anaemia, and complications such as phlebitis and urinary tract infections are not infrequent at this stage. The differential diagnosis cannot be discussed here, but it may be based on a detailed history, repeated inspection of the stools, microscopy and culture of the stools, and opaque enema. Digital rectal examination should of course be made, but sigmoidoscopy should only be carried out if the diagnosis is still in doubt after other investigations have been completed.

The notes of twenty-five cases have been studied. Sixteen of these patients have been observed personally during some period of their illness; all were females, many of them being treated at the Elizabeth Garrett Anderson Hospital.

Aetiological Factors

The age of onset was under 20 years in four cases, from 20 to 25 in four, from 26 to 30 in eight, from 31 to 40 in five, and over 40 in four. The cause of an attack was given by fourteen patients, and may be grouped as follows: a chronic tendency to diarrhoea, but attack due to eating fruit (two cases); chronic or acute constipation (six cases); gastric influenza (two cases); influenza (one case); slimming diet (one case); sea-bathing (one case); twin pregnancy (one case).

Special dietary indiscretions in some of the above were eating excess of raspberries, plums, tomatoes, and cucumber. Bargen³ has published the causes of relapse in a series of cases, and finds that the majority (52 per cent.) are related to infections of the upper respiratory tract, and 12 per cent. to gastro-intestinal conditions. The effect of trauma in producing an attack is evident when it occurs after taking food with indigestible residue. That colon lavage and sigmoidoscopy may also produce trauma and relapse is demonstrated in these notes. Colon lavage does not seem to produce harmful results in all cases, and patients may improve under treatment; but the results of local therapy are very uncertain, and a method which appeared to cure a first attack may be quite unsuccessful in a second. The benefits are at least doubtful, and such improvement as arises may be due to a spontaneous remission.

Relapse after Colon Lavage

One patient, aged 27, had had two previous severe attacks of colitis, but had been fairly well for fifteen months. She was thought to have a growth in the colon, and was admitted to hospital for examination. No growth was found, but there was a discharge of blood and mucus, for which daily lavage was given; acute relapse set in within three or four weeks and lasted many months. Two patients with chronic colitis were noted to have had normal motions for five and seven days respectively after admission; following colon lavage all the motions contained large amounts of blood and mucus. In one case the motions became normal when the treatments were stopped; in the other there was a prolonged relapse. In two other cases lavage brought about intense pain and increase in diarrhoea.

Relapse after Sigmoidoscopy

Sigmoidoscopy was carried out in fourteen patients in this series; in some it was repeated during treatment. All the cases showed a granular, intensely hyperaemic mucosa; three had small ulcers in addition; and one, a long-standing case, had rectal polyposis. Unfortunately an acute relapse may follow sigmoidoscopy even when carried out by experienced surgeons. One patient, aged 18, was admitted with a second attack of colitis of five weeks' duration; there were two motions daily after admission, with occasional blood, no fever; after sigmoidoscopy there was a severe relapse with fever: stools five to seven. Another patient of the same age had a first attack of colitis. The symptoms gradually increased for six months; there was no loss of weight and no fever: stools two to three; some blood. Sigmoidoscopy was followed by an acute fatal relapse: stools six to eight, with much blood and mucus.

Gastric Secretion and Colitis

No relation could be discovered between the gastric secretion and the severity of the colitis symptoms. In the present series fourteen patients had a fractional test meal: six had a normal acid reaction, six a low acidity, and two achlorhydria. Among the six normals, four had very severe attacks and the other two were chronic relapsing cases, and three in this group developed marked anaemia with oedema and phlebitis. Of the two patients with achlorhydria (histamine test not given), one had a slight attack without anaemia, and the other was a severe chronic case. In another case with dysphagia a "test vomit" contained no free acid; this patient had a very chronic colitis with Plummer-Vinson syndrome. Glossitis was noted in six instances, usually developing during an acute attack of colitis; it was most severe in two patients

with achlorhydria and chronic anaemia. Brittle nails were noted in four cases.

Anaemia and Colitis

The association of severe anaemia with diarrhoeal diseases with little or no haemorrhage is well recognized. It may in part be due to a deficiency associated with hurry and want of absorption in the intestine, but Castle⁷ has shown that the failure of haemopoiesis cannot be entirely related to this, but depends upon some associated though independent factor. Examples of such anaemias are afforded by tropical sprue, non-tropical sprue (Bennett, Hunter and Vaughan⁸), and chronic post-dysenteric colitis (Keefer⁹). The variability in the character of these anaemias is striking, and must depend on which of the essential factors is lacking. Further, it appears to be impossible to predict what form of therapy will prove effective, though as a rule a good response to liver may be expected when the anaemia tends towards the macrocytic group with a high colour index (as in Case 1). Massive oedema accompanying severe anaemia developed in three patients; two had phlebitis, and one a urinary infection.

Examples of Blood Changes

In five cases of anaemia without gross haemorrhage the haemoglobin values lay between 24 and 44 per cent., the red cells between 2,900,000 and 5,500,000, and the colour index between 0.4 and 0.56. These anaemias have all been hypochromic in type, such as respond well to massive doses of iron. Case 2 illustrates the importance of treating the anaemia, and the possibility of producing a prolonged or perhaps permanent remission of the colitis, even in a very chronic case. It should be emphasized again that a temporary increase in the diarrhoeal symptoms should not be regarded as a contraindication to treatment.

SUCCESSFUL TREATMENT WITH LIVER

Case 1.—The patient, aged 18, had acute colitis for eight months, with profound anaemia, oedema, and fever. There was a rapid clinical cure with massive liver therapy: no relapse after three years.

The first attack, sudden in onset, occurred in September, 1930, with the passage of blood, slight colic, and two to three stools daily. She continued at work for two months. In December, 1930, the anaemia was very severe; the stools contained blood and mucus; no specific infection. Sigmoidoscopy revealed a granular mucous membrane; one small ulcer was seen. Gastric acid was normal. For two months the symptoms gradually increased, with slight fever. Then there was an acute exacerbation, with fever up to 102° F. and pulse rate up to 125; stools six to twelve; not much loss of blood. Massive oedema developed, with rapid increase of anaemia: the increase of symptoms followed a course of daily colon lavage. In May, 1931, the oedema was better but there was still fever, the anaemia was unchanged and the patient had lost 2 st. Treatment during January to June included two blood transfusions and colon lavage; liver (4 oz.), ventriculin, and massive iron were each administered for short periods (coincidentally with the colon treatments), but were omitted as they appeared to increase the diarrhoea. In June, 1931, liver extract (1½ lb. daily) was again tried; it caused an acute reaction of fever and diarrhoea for eight days, but subsequently there was rapid improvement, with a gain in weight of about four pounds a week (2 st. in six weeks). When seen in April, 1934, the patient was very well, and had been free from any bowel trouble. Blood counts:—November, 1930: haemoglobin 27 per cent., red cells 2,500,000; colour index 0.56. June, 1931 (before liver treatment): haemoglobin 24 per cent., red cells 1,250,000; colour index 0.9. After two weeks of liver therapy: haemoglobin 36 per cent., red cells 3,130,000; colour index 0.58. Reticulocyte peak 13 per cent. on fourth day. After six weeks' liver and four weeks' massive iron: haemoglobin 70 per cent., red cells 4,580,000; colour index 0.76.

SUCCESSFUL TREATMENT WITH IRON

Case 2.—The patient, aged 45, had had a very chronic relapsing colitis for twelve years, and severe anaemia. Clinical cure was obtained with massive iron therapy: no relapse for four years. There was a history of severe constipation from childhood, and of anaemia. At the age of 29 she had the first attack of acute colitis, with much blood and mucus. At the age of 31 she had a relapse, and was treated by appendicostomy, which was closed after ten weeks. Subsequently chronic symptoms developed with severe anaemia: blood transfusions were given at the ages of 37 and 38. When 39 she first came under my personal observation, having frequent subacute attacks with slight fever. There was a typical Plummer-Vinson syndrome, with glossitis and dysphagia; a test vomit contained no free acid; haemoglobin 32 per cent., red cells 4,400,000. A full course of anti-dysenteric serum produced a strong reaction, but there was a relapse with blood and mucus two weeks later. In April, 1930, massive iron treatment was begun, and has been maintained almost continuously since. There has been no relapse of colitis in four years, although occasional slight bleeding occurs, and sore tongue and dysphagia reappear if the iron is omitted for long. The patient is able to do regular hard work. Blood counts:—March, 1928: haemoglobin 32 per cent., red cells 4,400,000; colour index 0.4. February, 1930: haemoglobin 38 per cent., red cells 4,400,000; colour index 0.43. December, 1930, after eight months' iron treatment: haemoglobin 106 per cent., red cells 5,650,000; colour index 0.94. Haemoglobin has been maintained between 90 and 100 per cent. since.

COMBINED TREATMENTS WITH IRON

Case 3.—The patient, aged 39, had been very anaemic all her life: no menses since the age of 35. She had always suffered from looseness of the bowels. In the first attack there was acute colitis for five months; phlebitis developed first in one leg and then in the other. There was much oedema on admission. Urinary infection was present; stools five to seven, with flecks of blood and very offensive. The patient was given two blood transfusions, intramuscular liver daily, massive iron, and radiostoleum. The haemoglobin rose from 24 to 80 per cent. in eight weeks, with marked general improvement; stools two to three.

Case 4.—This patient, aged 37, was seen in a second attack (first occurred twelve months previously). Apart from this her health had been good. She had a subacute colitis: stools one to two, with little blood or mucus. There was slight anaemia. She was treated with ventriculin and massive iron. The haemoglobin rose from 68 to 88 per cent. in five weeks; she gained four pounds in weight; the stools showed no marked change.

VITAMIN THERAPY WITHOUT IRON

Case 5.—The patient, aged 50, had had chronic colitis for three years, with very slight anaemia. Amoebic cysts were present in the stools (six to eight daily, with little blood). She was treated with emetine and yatrien, with severe reaction. At first liver was given intramuscularly daily, and yeast powder by mouth. Later, marmite and cod-liver oil were given. After nine weeks the stools were one to two daily—"better than at any time in the past three years."

Failure of Liver Treatment

The following three cases gave no apparent response to liver treatment during acute and subacute attacks; there was no initial anaemia.

Case 6.—The patient, aged 18, had had a first attack (very slight) one year before. She was admitted with a second attack of five months' duration (subacute). There was no anaemia. An acute relapse set in after sigmoidoscopy: stools seven to nine. Liver was administered intramuscularly daily, and yeast powder. The condition did not improve in three weeks. She lost 14 lb. in weight, and discharged herself.

Case 7.—This patient, aged 45, had had her fourth attack in five years; she was quite well between attacks. There was no initial anaemia. She had a severe haemorrhagic diarrhoea. stools three to six, later six to nine. Liver

JULY 28, 1934]

LATE TENDON SUTURE

extract by mouth (1 lb. daily) resulted in no apparent improvement in three to four weeks. There was gradual improvement later on other treatments.

Case 8.—This patient, aged 22, was seen in a first attack (subacute) of eight months' duration: stools two to four daily; slight anaemia only. Liver extract by mouth (1 lb. daily) led to no definite improvement in three weeks. She gradually got better later on other treatments.

Diet and Drugs

A good diet, adequately balanced, is of great importance. Many chronic colitis patients tend to take an excess of carbohydrate food, and care should be taken to avoid this. Patients should have small meals and never go long without food, and in particular they should avoid a heavy meal when fatigued. Iced food and drinks should be forbidden. Even during the acute attack, if appetite allows, a generous diet may be given, including as fish, eggs, chicken, and, later, mutton and beef. Small amounts of green-leaf vegetables (sieved), a cupful of orange or tomato juice, and marmite should be added. In convalescence fresh green-leaf salads, stewed fruit or pulped raw apple, pear, or banana may be ordered. The usual instructions to eschew food with coarse residue should be given.

Constipation should be treated with liquid paraffin and antispasmodics, as atropine or belladonna, especially when there is colicky pain. Mild aperients, as senna, are sometimes necessary, but should be omitted as far as possible. The dose of intramuscular liver was 2 c.cm. of concentrated preparation of tested potency in pernicious anaemia. In the massive iron therapy 90 grains of iron ammonium citrate were given daily. The yeast powder—a preparation of high potency in the vitamin B complex—was prescribed in doses of 3 drachms daily.

I am indebted to my colleagues at the Elizabeth Garrett Anderson Hospital for giving me access to their patients and records, and to the pathological staff of the hospital for their assistance.

The Queen Victoria Memorial Hospital at Welwyn, Herts, which the Duchess of York opened on July 24th, was founded in 1902. Until the present time it has been housed in the original building, to which additions were made from time to time. It is adjacent to a high road, which now carries a large amount of motor traffic. In consequence of a generous bequest made for the purpose of erecting an up-to-date cottage hospital in a quiet position, the committee was able to acquire an excellent site of about five acres and erect this new hospital.

The annual general meeting of the Medical Society of Individual Psychology was held at the Florence Restaurant, London, W., on July 12th. The chairman, Dr. J. C. Young, presided, and eighteen members dined together before proceeding to business. The present officers were re-elected. Dr. Neil Beattie and Dr. E. Taylor were elected to vacancies on the committee. The reports of the honorary secretary and honorary treasurer showed that the society is maintaining its position in membership and financial stability. An interesting programme is promised for next session.

LATE TENDON SUTURE

BY
ERIC I. LLOYD, F.R.C.S.

ORTHOPAEDIC SURGEON, ROYAL NORTHERN HOSPITAL; SURGEON,
HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET

Although delay in the suture of a ruptured tendon diminishes the chance of success, there are occasions when excellent function follows a delayed operation.

Rupture of the Triceps Tendon

The patient, a theatrical gymnast, sustained an accident while performing in a Paris music-hall. He was standing on his hands and supporting his partner's weight when he came upon a ridge in the carpet, which flung him sideways, so that he wrenched his left arm and tore his triceps tendon. The injury was apparently not diagnosed, and when seen three months later he had a gap of 1.2 inch above the olecranon process, and was only able to extend the elbow by the feeble action of supinator longus and the forearm extensors. He

FIG. 1.—Case 1. Rupture of left triceps tendon. Theatrical gymnast, aged 43, one year after reinforced suture performed three months after his accident.

FIG. 2.—Nearer view, showing situation of operation scar.

had done no work since the accident, and it was manifestly impossible for him to do so. X-ray examination showed a few flakes of the olecranon lying 1/2 inch proximal to their normal insertion.

At operation, on May 24th, 1933 (three months after the accident), the tendon was found to be torn so close to the bone that direct suture was impossible. A hole was drilled transversely through the olecranon, and a part of the tendon pulled down with strong catgut and threaded through this. Reinforcement was obtained by a length of half the width of peroneus longus tendon, which was passed through the bone and through two holes in the triceps tendon, and was then stitched both to tendon and to itself with catgut. The limb was left in extension for six weeks before exercises were attempted, but the patient then made such good progress that he was able to resume his occupation on October 1st, when he appeared at a music-hall at The Hague and considered his arm "normal" again. I have since seen his performance at a West-End music-hall, and he certainly did not spare his triceps.

The photographs were taken on March 24th, 1934, and show him supporting a 15-year-old boy a year after the accident.

Rupture of the Tendo Achillis

A tea-planter, aged 38, was playing deck tennis on the homeward voyage when he felt a pain in his left leg, and found that he was quite unable to stand on tip-toe. He was so pleased to be home again that his condition was not diagnosed until four months after the accident, and valuable time had been lost.

At operation, on May 20th, 1931, it was found that a gap of $1\frac{1}{2}$ inches in the tendo Achillis had been bridged by fibrous tissue. This was excised and the calf muscles mobilized, without, however, making direct apposition possible. The knee and ankle were flexed, but there was still a small gap to bridge. A length of $3\frac{1}{2}$ inches of half the peroneus longus tendon was passed through the two ends of the tendo Achillis, and a part of the proximal end of the tendo Achillis was turned down and sutured to its distal part. No attempt was made to close the sheath, and there was considerable difficulty even to get the skin together. The limb was put in plaster-of-Paris with the knee fully flexed and the ankle plantar-flexed. The knee was extended in a week, and the foot brought to 110 degrees two weeks later, when the stitches were removed and the plaster changed.

Eight weeks from the operation the patient was walking in an ordinary shoe, with the heel raised half an inch, but no plaster or apparatus. When he was seen four months after the operation he was wearing an ordinary heel, his foot was at 90 degrees, and he could stand on tip-toe on the affected side, bearing his whole weight on that foot for a fraction of a second. He had experienced no trouble, except for a stitch abscess, which was no doubt due to the mistake of using silk instead of catgut.

Bilateral Rupture of the Quadriceps Tendon

On March 18th, 1932, a Jewish shopkeeper, aged 77, and weighing 16 st., caught his heel on the stairs and slipped.

He had been unable to extend his knees since the accident, and walking was out of the question. He was very depressed by reason of a gloomy prognosis, based on the assumption that he had a haematomyelia of the cord and would never walk again.

At operation on the right side, on June 6th, 1932 (two and a half months after the accident), the quadriceps tendon was found to be torn at the actual point of insertion into the patella, making it necessary to drill a hole in the patella and suture the tendon with strong silk. This suture line was reinforced with fascia lata, and the capsule of the joint closed with catgut. Two weeks later the left side was operated upon, and a complete rupture disclosed and repaired.

A year later the patient was seen at his little shop in Holborn: he could walk without sticks, and had active extension of the knee through 30 degrees. He did, however, generally use sticks for walking, as he felt somewhat insecure, no doubt partly owing to his age and weight.

FIG. 3. — Case III. Bilateral rupture of quadriceps tendon. Sixteen-stone patient, aged 79, nearly two years after delayed and reinforced suture. Operation two and a half months after accident. He can stand unaided, as shown.

Comment on Delayed and Reinforced Tendon Suture

The successful results in these three cases are no argument for delay in suturing cut or ruptured tendons. The diagnosis of such an injury ought to be followed immediately by operation in any recent case. If, however, diagnosis or treatment has been delayed, there is still a good chance of getting a satisfactory result, even two or three months after an injury of the large extensor tendons. The story is an altogether different one for the smaller tendons, which are concerned with fine movement, such as those of the hand.

Operative Technique

The exact operation will vary in different cases, but the following points in technique seem reasonable.

1. The functional efficiency of a muscle demands apposition of the torn ends of the tendon whenever possible, and, failing that, the shorter the bridge the stronger will be the muscle.

2. Aids in securing apposition. Posture of adjacent joints and mobilization of muscle bellies help, but good honest pulling on the muscle generally helps more.

3. Suture material. Strong chromic catgut is the best, but it must be supported by splint or plaster-of-Paris for six weeks. Weight-bearing may be allowed during the latter half of the period if the sutured tendon is in the lower limb.

4. Supplementary sutures. Peroneal tendon and fascia lata will sometimes turn doubt into security. They are always available in case of need.

5. The immediate post-operative position of a joint should relax the suture line, but if such is a malposition it must be gradually corrected in two or three weeks if the patient is an adult. In children this is not so essential.

6. It is much better to put the tendon through a hole in the bone than to stitch it to periosteum.

A SECOND ATTACK OF ACUTE POLIOMYELITIS

BY

THOMAS MOORE, M.B., B.S.

CLINICAL ASSISTANT TO THE ORTHOPAEDIC DEPARTMENT, ROYAL VICTORIA INFIRMARY, NEWCASTLE-UPON-TYNE

The occurrence of a second attack of acute anterior poliomyelitis is rare.* In 1930 Still¹ reported one case, and was only able to collect eight definite cases from the literature. The diagnosis depends entirely on clinical evidence. In the case here reported this seems to be so complete as to leave no doubt as to the diagnosis.

Case Record

History.—On February 14th, 1934, W. L., aged 7 years, was brought to the out-patient department of the Royal Victoria Infirmary, Newcastle, because he was paralysed. His mother volunteered the following history. The child was healthy at birth, but at 10 months of age he had an attack of pneumonia. He was ill for fourteen days. After this the lower limbs seemed to "pine away," and he did not progress normally with learning to walk, as he had been doing previously. When the child was 3 years old he walked so badly—"his feet just seemed to flop about"—that his mother took him to see Dr. Natrass at the Royal Victoria Infirmary (April 5th, 1930). He was given massage treatment and fitted with iron splints. He was able to walk remarkably well in these, used to go to school in them, and lived as a normal boy until eight weeks ago. He was then sent home from school because he was not well. The mother noticed that he was "heavy" and feverish, and his nose was running. A doctor who was called in thought he was sickening for measles. In a day or two, however, he improved, and returned to school after a week's absence. A week later the child was taken ill again, and had to be put to bed. On the third day a rash appeared, which was diagnosed as measles. The child became very weak and helpless, and unable to feed himself. He complained of pains in his back and limbs, which were sore to the touch. After fourteen days an attempt was made to get the child up. It was then found he could neither stand nor sit.

* A short case record appeared in the *Epitome of Current Medical Literature* of June 9th, 1934, para. 474.

A SECOND ATTACK OF ACUTE POLIOMYELITIS

JULY 28, 1934]

Clinical Findings (February 14th, 1934).—Examination revealed a rather pale child of normal intelligence. No abnormality could be detected on examination of the respiratory, cardiovascular, or alimentary systems. The cranial nerves were found to be normal. Examination of the upper limbs was as follows. The proximal muscles were normal, and of the hands there was marked wasting of the interossei, and of the thenar and hypothenar eminences, so that the hands appeared flattened. The fingers were held in slight flexion at the interphalangeal joints, and hyperextension at the wrists and phalangeal joints. The power of flexion of the left hand fingers was weak. There was no power at all in the left interphalangeal joints, and attempts to do so only resulted in an increase of the claw-hand deformity. He was able to extend the flexor carpi ulnaris. The patient was unable to extend the interphalangeal joints of the fingers or flex the metacarpo-phalangeal joints. There was no power of adduction or increase of the metacarpo-phalangeal and the interphalangeal joints of the thumbs. There was marked wasting of joints of opposition of the thumbs. There was hyperaesthesia to both lower limbs, and each showed the deformity of talipes equinovarus. There was some cutaneous hyperaesthesia moving touch of the left lower limb. Both quadriceps hip-joints were very much reduced in power, particularly on the left side. All the muscles moving ankle and tarsals and hamstring muscle groups were very weak, particularly on the left side. All the muscles moving ankle and tarsals joints were completely paralysed save the left posterior tibialis, which had a trace of power. There was no power in the recti abdominis.

Electrical Reactions (April 24th, 1934).—There was no faradic response in the muscles of the legs and (?) no galvanic response. There was no faradic response in flexors of the right wrist or fingers, but some in the flexor carpi radialis. No faradic response occurred in the muscles of the right hand. There was fair galvanic response. Faradic response was present in all flexors of the left wrist and fingers, there being no faradic response in the muscles of the left hand. The galvanic response was fair.

It was particularly fortunate that this child was originally seen in the hospital, for the following clinical findings, made on April 5th, 1930, are available. "A case of anterior poliomyelitis—atrophy weakness of both lower limbs, double paralytic talipes equinovarus." The electrical reactions recorded at the same time are given as follows. "Right leg—no faradic response in extensor digitorum longus, and posterior tibialis; or peronei; good response in anterior and posterior tibialis; faint response in calf muscles; galvanic response rather poor. Left leg—no faradic response in anterior tibialis or peroneal muscles; good in calf muscles; long flexor doubtful; galvanic response rather poor."

The child was given the usual physical treatment, and was fitted with double irons to the right knee and full-length irons on the left leg attached to pelvic band.

Conclusion

From these findings there appears to be no doubt that the child, at an early age, had an attack of acute anterior poliomyelitis. This left him with some weakness of the lower limbs, but he was able to walk remarkably well in supports, and lived as a normal boy until nearly 7 years of age. Then, following two rather indefinite febrile illnesses, the muscular weakness became much more widespread. The affection of the lower limbs increased in severity, and the hands and recti abdominis were affected in addition. In consequence the child was left in a very helpless condition. While he has been in hospital the condition of the limbs has not improved, but the recti abdominis are recovering slowly. There would appear to be no other explanation of these findings but that a second attack of acute anterior poliomyelitis has occurred.

My thanks are due to Mr. Gordon Irvin, under whose care the patient is, for permission to publish the case, and to Dr. F. J. Nattrass for his helpful advice and criticism.

Clinical Memoranda

A MODIFICATION OF BENEDICT'S TEST

In most laboratories either Fehling's reagent¹ or Benedict's qualitative reagent² is used in making a preliminary rough estimate of the amount of sugar in the urine, but with the application described below I have been able to dispense with the standard quantitative determinations altogether in routine clinical work. The method depends on observing the colour of the filtrate obtained after boiling the urine with Benedict's qualitative reagent. By experiment it was found that 5 c.cm. of the reagent is just decolorized by 0.5 c.cm. of 2 per cent. glucose (that is, 10 mg.) in five minutes in a boiling-water bath.

TECHNIQUE OF TEST

Five c.cm. of Benedict's qualitative reagent and 0.5 c.cm. of urine are mixed in a test tube, which is placed in a boiling water bath for exactly five minutes. The mixture is filtered hot through a fine paper (Whatman No. 44) into a tube of the same bore as that of the standard colour tubes. The colour of the unknown is then compared with that of the standards, the tubes being observed against a white background. If the filtrate is colourless 2 per cent. or more of glucose is present; the test is therefore repeated, employing urine which has been diluted twofold or fourfold, and allowing for the dilution in the calculation. The preparation of the standard colour tubes and the concentration of sugar to which each corresponds will be clear from the following table.

No. of Standard Tube	Amount of Benedict's Solution (c.cm.)	Amount of Distilled Water	Percentage of Glucose to which Tube Corresponds
		0.5	0.0
1	4	1.5	0.4
2	3	2.5	0.8
3	2	3.5	1.2
4	1	4.5	1.6
5	0	5.5	2.0 or over
6			

The above data have been established by direct experiment. Thus it was found that the colour of the filtrate, after heating 5 c.cm. of reagent and 0.5 c.cm. of 0.4 per cent. glucose in a boiling-water bath for five minutes, exactly matched the colour of a mixture of 4 c.cm. of reagent and 1.5 c.cm. of water; and so on for the other tubes. The filtrate may have a greenish tinge which, when marked, renders matching with the blue standards rather difficult. Nevertheless, the accuracy that can be attained by this modification is always sufficient for clinical purposes. The only special apparatus required is a set of six uniform tubes containing the standard solutions. These can be readily prepared from the table given above.

I wish to thank Dr. G. A. Harrison for providing the facilities for doing this work in the Laboratory of Chemical Pathology at St. Bartholomew's Hospital. A compact outfit, comprising a set of standards fixed in a suitable stand, filter paper (No. 44), small filter funnels, and tubes uniform with those containing the standard solutions, can be obtained from British Drug Houses, Ltd., Graham Street, London, N.1.

JOSEPH FINE, M.D.

St. Bartholomew's Hospital.

Reviews

GENERAL ANAESTHESIA

Privatdozent HANS KILLIAN's textbook on general anaesthesia, *Narcosis for Operative Purposes*,¹ shows evidence of balanced judgement and outlook, with much experience of both clinical and experimental work. The author's wide reading is shown by the liberal documentation to every chapter, and indeed it may be questioned whether the book is not overloaded with references, though, as he states, the literature on the subject is terrific (*ungeheuer*). The history of anaesthesia and of the various agents and methods employed is concisely and fully given; recent innovations are mostly described, excepting divinyl ether, while pending further experience judgement on cyclopropane is withheld. The author explains that the development of the specialty in Germany has been hindered by economic and other causes, and that operating surgeons generally demand as complete a control of the anaesthesia as of the operation, while specialization is often condemned. Though he states here that the future will show whether these conditions really make for the benefit of patients, in a later chapter he ascribes the failure to make use of nitrous oxide in dental work largely to the absence of specialists.

The arrangement of the book is rather unusual, for the theoretical aspects of narcosis as a whole—chemistry, physics, absorption, elimination, etc.—are very fully and completely described and illustrated with graphs, charts, and tables, as are its effects on the various systems and on the metabolism. The technical side is also fully dealt with—namely, the preparation of the patient, stages and progress of anaesthesia, signs of depth, and so on. In regard to the latter, eye signs rightly appear very low down on the list, while alterations in breathing are placed high. A transatlantic flavour is given, among other things, by the graphic schemata for the course of anaesthesia with the various agents. The prevention and treatment of complications are described.

The amount of space given to the details of administration contrasts strongly with that devoted to theory; thus, although the technical chapter comprises 100 pages, the allotment of space for practical instruction is as follows: Ether, "open" nine lines, Ombredanne fifteen, vapour methods twenty-eight. Chloroform has one line only—"The use of chloroform in clinical practice is forbidden," a verdict which many may think too harsh. Nitrous oxide, including gas-oxygen, has eight lines. The use of 100 per cent. gas for induction is condemned, while throughout the book particular emphasis is laid on the need for the avoidance of cyanosis and for the maintenance of high oxygen percentages, an opinion which may not be shared by all authorities. Ethylene has three lines, narylen (acetylene) five, and others in proportion.

The statistics of anaesthesia, also its deaths, complications, and sequelae, are fully and cautiously discussed, while the comparative mortality figures are very fairly given. The use of methods other than narcosis is considered, without bias, for various operations and regions. A section on therapy makes no reference to the use of carbon-dioxide-oxygen mixtures in asphyxia neonatorum.

The author's attitude towards basal narcosis is conservative, and he considers that, although the barbiturates give good results with gas, their use has increased the mortality and morbidity rates for ether (though lack of skilled administrators may not be without influence here). Avertin is condemned for chest surgery, owing to its depressant effect on an already hampered respiratory

system, and in general he considers that its use will decrease in future. Nembutal is not mentioned. Evipan (endorm) is justly praised as the most valuable of the barbiturate series at present, and though the use of after-doses is described, no extravagant claims are put forward.

Though there is not the customary textbook display of small instruments, a fairly complete range of gas and other apparatus is illustrated, but no complete British machine, with which the author is evidently unfamiliar, since though two small ones are shown, one is described, but quite incorrectly, while the other, which is said to be similar, is in fact totally different in design and construction (pp. 377-8). The mouth-hook on a nasal gas fitting is strangely described as a suction tube (p. 373). The author's machine appears well designed and practical, but the block of his sight-feed is upside down (p. 361). He is not at all enthusiastic about carbon dioxide absorption methods, but advocates the exhaustion of expired gases from the machine, or mask. A novel principle described is the use of anaesthesia under negative pressure for producing anaemia during cerebral operations. Tracheal insufflation and intubation are described, but there is no mention of Magill's "blind" method. It is admitted that the former prejudice against tracheal methods in Germany was unjustified, and that they should be more widely used. The mode of intubation described (p. 343)—namely, to insert the spatula between the cords and then to twist it so as to separate them widely—will hardly commend itself to English readers. A chapter on explosions and safety precautions stresses a danger which has had little attention here.

PARSONS'S "DISEASES OF THE EYE"

It is a pleasure to extend a welcome to the seventh edition of Sir J. HERBERT PARSONS's manual of *Diseases of the Eye*.² Four years have passed since the sixth edition appeared, and during these four years ophthalmology has seen considerable advances. It is one of the best features of this book that the essentials of the new knowledge are incorporated in each successive edition without adding to its bulk or changing its character. As has been said in previous reviews, its lucidity, its comprehensiveness, and its compactness make this an ideal textbook for the student as well as an excellent reference book for the practitioner, while its worth is enhanced by the absence of polemic discussions of theoretical matters of temporary interest or questionable value, and by its insistence on the practical points of diagnosis and treatment as these affect the everyday practice of ophthalmology. What is new is not added to the text inconsequently, but it is sifted and assessed by a mind of unusual critical power in the light of an experience which it would be difficult to parallel. The book has always been considered the best manual on its subject in our language; the new edition will carry on this tradition, and well deserves to do so.

DETERMINATIVE BACTERIOLOGY

Most bacteriologists, at any rate those concerned with the teaching of this subject, are already acquainted with BERGEE's *Manual of Determinative Bacteriology*.³ All will admit the necessity for the introduction of order into the chaos of bacteriological classification. Unfortunately the system elaborated by the Committee of the Society of American Bacteriologists, which this manual presents, has not received universal sanction; even the society itself

REVIEWS

JULY 28, 1934]

points out that the system is in no sense official or standard. However, opinion for and against what has come to be known as the American system of classification crystallized out long ago, and in introducing the fourth edition the duty of the reviewer is mainly confined to announcing its appearance. This new edition contains additions and modifications. Two new genera have been recognized—*Brucella* and *Listerella*—and the genus *Pfeifferella* has been combined with *Actinobacillus*. Many new species have been included, and some organisms have lost their specific status. However, those interested will consult the book and see for themselves the advances which have been made.

"ANNALS OF MEDICAL HISTORY"

The May instalment of the *Annals of Medical History* opens with an extremely interesting but hitherto somewhat neglected subject—the costume and outward trappings of medical men; Mr. W. J. Bishop has here brought together a great deal of information from many sources, including the Royal College of Physicians of London, and has introduced some lively quotations and episodes. Dr. H. E. MacDermot of Montreal contributes an attractive analysis of the early editions of Osler's *Textbook of Medicine*, and from a study of the author's own copies in the Osler Library at McGill traces the changes in the successive editions, and brings to light many of Osler's quips and turns of speech. In the next article Dr. Pitfield gives a sketch of the life of Dr. T. H. Chivers, "the wild Mazepa of letters," also described as being "at the same time one of the best and one of the worst poets in America" in the first half of the last century. Dr. W. E. Robertson's article on physical diagnosis from the time of Röntgen is not such modern history as the title suggests, for reference is made to the activities of medical pioneers before the discoverer of x rays was born; a number of eponymic physical signs are mentioned, among them Riesman's sign in exophthalmic goitre, which are unfamiliar to many medical men. The state of treatment in this country, as judged by John Wesley's popular *Primitive Physic* (1772) is compared with that in Persia at the beginning of the sixteenth century, as shown in Joseph of Herat's work on therapeutics, by Dr. H. A. Lichtwardt of Meshed, who arrives at the rather startling conclusion that there was not much difference between them. Dr. B. W. Weinberger of New York contributes a well-illustrated article on ancient dentistry in the *Old World*, and Dr. Lynn Thorndike provides a glimpse of the state of medicine in the third quarter of the seventeenth century by analysing the *Bibliographia Medica et Physica Novissima* (1681) of Cornelius a Beughem.

MOVEMENT, MANIPULATION, AND MASSAGE

Written as a handbook for the qualified masseur and in the hope of interesting medical practitioners in the prescribing of massage for their patients, Dr. J. B. MENNELL's *Massage, Its Principles and Practice*, has become the standard English book on the subject. It was published during the war, and was then remarkable for the progressive views which have wrought such a change for the good in the treatment of recent injury, and have aided so many disabled men in recovering the greatest possible measure of functional activity.

A third edition has now appeared, under the new title of *Physical Treatment by Movement, Manipulation, and Massage*. New Series, vol. vi, No. 3, May, 1934. Edited by Francis R. Packard, M.D. New York: Paul B. Hoeber, Inc., London: Baillière, Tindall and Cox. (Pp. 193-290; illustrated. Volume of six numbers, £2 15s.; single number, 12s. 6d.)

Massage.⁵ This change is a happy one, for it indicates the more comprehensive nature of the contents, the earlier title having suggested treatment limited to massage in the more restricted sense of the term, although the book actually covered a wide field of physical treatment. The new edition has been greatly augmented, and much has been rewritten. Some wholly new chapters have been added, including a timely one on "the use and abuse of the faradic current," which comprises a description of the technique of applying the faradic current for one of its lesser-known properties—namely, its sedative effect and its use in teaching relaxation. A new section on "referred pain from the back" has been added to the valuable account of the problem of backache, and the importance of the two chapters devoted to this subject cannot be too highly stressed. The simplified diagrams illustrating them are clear and telling. Another new chapter which will be welcomed deals with joint manipulation. Concerning physical treatment in obstetrics and gynaecology, the detailed prescription for measures to be adopted during the puerperium gives exactly the information most helpful to a masseuse who, after qualification, may for the first time have an opportunity of administering this very beneficial prophylactic treatment. Altogether, the third edition of Dr. Mennell's book is a distinct advance on the original edition, admirable though the latter was, and it ought to be possessed and seriously studied alike by the experienced masseur and the medical practitioner.

LEPROSY CONTROL IN MALAYA

The Government of the Federated Malay States has issued a booklet⁶ describing the Leper Settlement at Sungei Buloh in order to record the steps that have been taken to fight this disease and with a view to assessing so far as is possible the extent to which the effort is proving successful. The Settlement was completed in 1930 in conformity with the Malayan law that every leper must be segregated. After eliminating from the valley in which it was placed all breeding grounds for the *Anopheles maculatus*, and the eradication of indigenous malaria, fifty-seven acres were taken over for the necessary living houses, farm area, fruit plantations, enclosures for rearing live-stock, administrative buildings, treatment blocks, and playing fields. There is accommodation for nearly a thousand lepers, obtained at a cost of about £100,000. Most can walk about, and assist in the conducting of the Settlement life, but for advanced cases and the sick there are two specially constructed wards for men and one for women. The principles of modern town planning have been skilfully introduced into the Settlement, no monotonous streets or dull blocks of houses being permitted. There is no suggestion of control by coercion; the settlement is not on an island, there is no wall, and no outside guards or police between it and the main road to Kuala Lumpur. Yet very few lepers attempt to escape, and most of those who do so return voluntarily in a short time. Ample opportunity is given for recreation, and the work and partial control of the Settlement is in the hands of the lepers. There are five social clubs and an open-air cinema; dramatic entertainments are arranged from time to time, with obviously beneficial results on the health of the leper children. Educational facilities are provided. The workers in the Settlement receive a small monthly payment.

Discussing the problem of marriage among lepers, Dr. G. A. Ryrie, who has been medical superintendent for *Physical Treatment by Movement, Manipulation, and Massage*. By J. B. Mennell, M.A., M.D. Third edition. London: J. and A. Churchill Ltd. 1934. (Pp. 618; 274 figures. 21s.)

⁵ *Physical Treatment by Movement, Manipulation, and Massage*. By J. B. Mennell, M.A., M.D. Third edition. London: J. and A. Churchill Ltd. 1934. (Pp. 618; 274 figures. 21s.)

⁶ Malaya Publishing House, Ltd., Singapore.

most of its existence, and has drawn up the booklet, defends the provision of married quarters. He points out that no child is ever born with leprosy, but it is necessary to remove such children from their leprosy parents in order to prevent infection. The birth rate is low. Children born in the Settlement are removed after two weeks to the General Hospital in Kuala Lumpur, where they are cared for at Government expense. When the parents are discharged from the Settlement their children are returned to them; others are adopted by benevolent families outside. Patients are encouraged to look forward to ultimate discharge; they are considered free to leave after having been for six months free from symptoms both clinically and bacteriologically. On discharge a patient is given a railway ticket to his home and a certificate to his previous employer. There are a dozen leper "policemen," who organize exercise groups, help the older people and the children, act as messengers in the Settlement, and generally promote an atmosphere of courtesy and good will. In these ways a small staff controls happily and successfully a thousand patients who are legally in detention, even though there are at least six different religions and a babel of languages. All except the most hopeless cases are under treatment, and research is in active progress on this mass of clinical material. There are special centres for teeth disorders, the treatment of venereal diseases, children, and sores of the hands and feet.

Dr. Ryrie discusses the interesting topics that arise in connexion with this modern way of tackling a national problem. The success achieved is indicated by the steady rise in the number of voluntary admissions. The Settlement educates the leper in the way he should live, and sends him out to carry the information to others. In no other country does the same field exist for the investigation of the different racial varieties of leprosy, for the observation of relative incidence and its causes, and for the consideration of the effects of national diets and habits on the course of the leprotic process.

Notes on Books

In his little book *Studies in Blood Formation*⁷ Dr. T. D. POWER describes and discusses his observations on the administration of sulfosin, thyroxine, and indian ink to rabbits and man, and also the blood changes that follow the treatment of general paralysis by malarial parasites. These observations do not advance our knowledge of blood formation, and the discussions involve amateur speculations of little value. The introductory chapters, which are concerned with haematological technique and the histology of the blood and bone marrow, are superfluous, and will not appeal to haematologists familiar with these subjects. The cytology of the bone marrow cannot be studied satisfactorily in sections. The author does not make it clear that reticulocyte formation *always* precedes the formation of mature red cells, but the appearance of reticulocytes in the circulation depends largely on the rate of maturation of these cells in the bone marrow.

The latest addition to the historical series of *Clio Medica* is the little book on *Japanese Medicine*,⁸ by Dr. FUJIKAWA, which first appeared in a German form in 1911, at the International Health Exhibition held at Dresden, and has now been translated into English by Professor RUHRÄH, with a supplementary chapter on recent medical history in Japan by Dr. KAGEYAS W. AMANO. The book is divided into ten chapters, devoted to the history of medicine in Japan from remote antiquity down to the

⁷ *Studies in Blood Formation*. By T. D. Power, M.D., M.R.C.P., D.P.H., D.P.M. London: J. and A. Churchill Ltd. 1934. (Pp. 124; 25 figures. 8s. 6d.)

⁸ *Japanese Medicine*. By Y. Fujikawa, M.D. Translated from the German by John Ruhräh, M.D., with a chapter on the recent history of medicine in Japan by Kageyas W. Amano, M.D., D.Sc. New York: Paul B. Hoeber, Inc. 1934. (Pp. 114. 1.50 dollars.)

present day. At first all medical lore came out of China, but from the seventeenth century onward European practitioners, especially the German and Dutch, who came to Japan as physicians to their respective embassies, had considerable influence in the development of Japanese medicine. The chapter on the recent history of medicine, by Dr. Amano, contains an illustrated account of the work of Shiga, Takamine, Kitasato, Noguchi, Inada, and Ido, among others, and a list of Japanese medical schools. A chronological table of the chief works in Japanese medicine, from 413 B.C. to the present day, is appended.

A review of the many medicaments of every description that have been used in the treatment of arterial hypertension is furnished by Professor ROCH⁹ of Geneva, and should be of service to medical practitioners anxious to try yet another treatment for this chronic malady. The book is well written, and the indications for the various lines of treatment suggested are clearly described.

In a thesis on Local Treatment of the Lung¹⁰ Dr. VICENTE DE PABLO maintains that the modern method of local treatment of the various accessible organs should logically be applied to the lung. The only method hitherto employed has been that of tracheo-bronchotherapy, which has been carried out by relatively few persons, owing to the difficulties in its performance. On the other hand, the transglottic method of Garcia Vicente, adopted by the author, is simpler, and enables the treatment to be applied directly to the trachea, bronchi, lungs, a single lung, or a single lobe. A bibliography of 107 references is appended.

Mr. C. L. HINTON, of the British Association of Research for the Cocoa, Chocolate, Sugar, Confectionery, and Jam Trades, has compiled a *Summary of Food Laws and Regulations*, and this is published at the high price of one guinea by the Nema Press Ltd. (33, Tothill Street, London, S.W.1).

⁹ *Les Traitements de l'Hypertension Artérielle*. By Maurice Roch. Paris: Masson et Cie. 1934. (Pp. 128. 20 fr.)

Preparations and Appliances

A NEW LIGHTED VAGINAL SPECULUM

Mr. M. DATNOW, F.R.C.S. (Liverpool), writes: For the purpose of simplifying the demonstration of the cervix and its lesions to students, I have had made for me by Messrs. Alexander and Fowler, Liverpool, the speculum illustrated below. Its advantage is that it is compact and simple to sterilize, as the whole instrument, except for the battery, can be boiled. The parts are easily detached and there is nothing

to go wrong. The battery is contained in the handle (a); the cap (d) acts as a switch and has a hook attached on which may be placed a weight so that, for operating purposes, the speculum can be retained with the patient in the lithotomy position. The other parts are the light (b) and a detachable blade (c), which can be procured in different sizes.

Inspection of the cervix, vaginal fornices, and anterior vaginal wall are greatly facilitated by this instrument. I have

PREPARATIONS AND APPLIANCES

JULY 28, 1934]

also found it very useful in operations in nulliparae and persons with narrow vaginae, where a light which occupies no room is a distinct advantage. There is no doubt that inspection of the cervix will not infrequently reveal a small polyp or ulcer that is missed by palpation. The omission of cervical inspection during gynaecological examinations frequently leads to important lesions being overlooked in the early stages. I hope that this speculum, by facilitating inspection, will encourage this procedure.

AN ECONOMICAL DESIGN OF THE MELTED PARAFFIN WAX BATH

Sir LEONARD HILL, M.B., LL.D., F.R.S. (Supervisor, St. John Clinic and Institute of Physical Medicine, Ranelagh Road, London, S.W.), writes:

Treatment by application of melted paraffin wax was first carried out in France. Some years before the war Mr. W. L. Ingle noticed that many of his workpeople were in the habit of immersing their hands and feet in a vat of wax, which was at his works at Cherwell, Yorkshire. The vat had a holding capacity of half a ton, and steam was used for heating it. So many were benefited by it that Mr. Ingle, during the war, presented the bath to the 2nd Northern General Hospital for the use of wounded soldiers, and Colonel Littlewood found it of considerable value in giving relief in cases of neuritis and rheumatism. Stiffness of muscles and

joints, due to wounds, nerve injuries, and splinting, and vasomotor troubles such as frost bite were benefited. Dr. Howard Humphris, having seen this bath, had one made for his use in London, and in a lecture given in 1919 stated that he had found it useful for chilblains, neuritis, rheumatic and gouty joints, fibrositis, cramp in the calf and intermittent claudication, eczema vesiculosum, and phlebitis. The bath was made of white glazed fire-clay, 3 inches thick (to prevent radiation of heat), and was fitted with a self-contained heating apparatus which kept the wax at the required temperature (120° to 130° F.). If the melting-point of the wax is 110° when the patient immerses, say the hand, in the bath for twenty to thirty minutes the wax forms a glove of solidified wax on the part, and the vapour under this acts as an insulator and prevents burning. The sensation of heat is thus quite comfortable. When the part is removed and allowed to cool for two to three minutes the wax coating is easily peeled off. The bath itself is thus not contaminated, while the wax peeled off the patients is reddened, moist, and somewhat greasy, and in ideal condition for massage. The patient usually experiences relief from pain, and finds the joints more limber. Patients with nerve lesions can stand only 115° to 118° without blistering, while others can stand 130°, and even up to 140°.

Immersion of a part in the bath, according to Dr. Howard Humphris is a better form of treatment than pouring melted paraffin wax on to it.

The paraffin-wax bath has been found costly to run, and I have been told of a general hospital being forced to give it up on that account. The excessive cost is due to the

amount of current required for keeping the bath hot. It was obvious that the cost might be very much lowered by proper insulation. Glazed firebrick is a good insulator for high but not for low temperatures.

With the help, then, of Mr. H. Saunders of 205, Chichester Road, N.9, an engineer well versed in problems of insulation, a bath was so constructed that the cost of electric current for running it was only 1s. per week when the bath was covered and not in use, and under 6s. per week when one hundred treatments per week were being given.

The bath consists of a water-jacketed tank, whose inside dimensions are 4 ft. 6 in. long, 2 ft. 3 in. deep, and 2 ft. 6 in. wide, provided with electric heaters in the jacket wall, which heat the water, W, with which the water-jacket is filled. The water-jacket is 3 in. wide at the sides and 5 in. at the bottom. The outside of the jacket is packed with cork, C, insulation 4 in. thick, and finished with panelling.

The working temperature of the bath is controllable by means of the adjustment screw and dial on the thermostat, T, the stem of which projects into the water-jacket, a removable panel being provided to enable it to be readily accessible for adjustment and change of working temperature. The thermostat controls the circuit breakers, 1, 2, 3, which are arranged on the switchboard on the wall of the room, and the electrical wiring from the board to the thermostat and heater is enclosed in conduit. The operation of the heating

system and control is illustrated in the circuit diagram, and their arrangement may be followed from the equipment figure. In addition, a gauge glass, G, filling tube, I, and overflow, D, are provided, these being arranged in another removable panel box above the heater panel.

All elements and components to the heating and water system are interchangeable, and easily accessible to enable their replacement in the event of defects arising—a comparatively simple matter. The wax, which is surrounded by the water-jacket, never comes in contact with any temperature above that at which the water is held; thus no danger can arise from volatilization or fire, and as the area for heat transmission is very large the heat recovery is more efficient. As the usual range of temperature working is approximately 130° F. the water evaporated is not very much, and it is not necessary to provide a permanent connexion to the water supply. Loss of water observed in the gauge glass can easily be made up by feeding water by hand into the feeding tube, I, to the required level. For immersion of the legs a broad seat and back support is arranged at one end of the bath. There are steps, too, at the side of the bath on which patients can stand for the comfortable immersion of their arms. A wooden cover for hand or leg can be constructed by Mr. Saunders on the same principle, and made movable.

The patients at this clinic report very favourably of the wax-bath treatment. The clinic, which was known as the London Clinic, has now been named the St. John Clinic, as the control of the clinic is under the Order of St. John.

British Medical Journal

SATURDAY, JULY 28th, 1934

THE PRESIDENTIAL ADDRESS, 1934

The opportunity given him by his high office naturally leads a President of the British Medical Association to strike a topical note. Often the place at which the Annual Meeting is held is the inspiration of the address. Sometimes the occasion is used for dealing with the special department of medicine in which the President is interested, or for reviewing the progress of medicine or of the Association during the interval which has elapsed since a previous meeting at the same place. Dr. S. Watson Smith, in taking as his subject "Climate and Health," has happily chosen one peculiarly fitted to a place which is perhaps the best example in this country of a health resort richly endowed by nature, which was deliberately created as such and has been developed by the labours of several generations of vigilant and far-sighted citizens. Moreover, the subject is very suitable to a period when physical medicine, of which the study of airs, waters, and places constitutes a very important part, is receiving so much attention. There can be few places, outside the spas of the country, in which such a subject could so fitly be treated, especially as it was followed on Wednesday morning, in the Section of Balneology and Climatology, by a discussion which may be said to be complementary to much that is contained in the Presidential Address.

Dr. Watson Smith's brief reference to those problems of public health which were debated at the Bournemouth meeting of 1891 is a useful reminder, to which the rest of his address can be regarded as a corollary, that the advance of medical science is definitely orientated in the direction of the prevention of disease, largely by means of the improvement of environment. His faith that the British Medical Association can be trusted to be mindful of its responsibility to the public will be a fresh stimulus to a body which is justly proud of its past history, and which has shown by its actions that it is aware that its status depends quite as much on its exhibition of public spirit as on its capacity to promote and defend the interests of the medical profession and its members.

Running through the whole of the address is the belief that the use of what may be called nature's remedies can and should be put on a more scientific basis: that the old empiricism which has too long been associated with this group of remedies is out of date. And it is very useful to have the President's comprehensive definition of climate as "all the solar and terrestrial factors and influences which affect animal and vegetable life, including sunlight, atmospheric temperature, humidity and pressure, movement of the air, and prevailing winds—the factors which make our climate what it is; and . . . also embracing waters and

places." Here, indeed, is a wide field for research, comparatively untilled, which should attract the attention of local workers, for they alone can provide many of the necessary data and help to draw the conclusions which should prove useful to all doctors who have to advise as to choice of a health resort.

The President's interesting, but necessarily rapid, review of the value attached by the fathers of medicine to climate and waters will serve to remind us that there is nothing new under the sun, and also that there were wise men in a generation even more empirical than our own. His passing allusion to the influence of environment on mental reactions is all too brief, and well deserves further elaboration; and the remarks on the influence of climate on national character may give food for thought to those who see in our climate mainly a subject for sardonic humour or idle "grousing." Even our national genius for self-depreciation cannot obscure the fact that the very changeableness and relative absence of extremes of the climate of Britain has bred one of the hardiest and most self-reliant races in the world. There is a real topical interest in the remarks on the dangers of over-radiation. It is possible to have too much of a good thing, and the medical profession knows that the fashionable cult of the sun is not without its drawbacks. All means of treatment that are potentially useful are potentially dangerous if abused, and it is to be hoped that the President's remarks on this subject will reach a wide public. Many holiday-makers spend too much of their time trying to persuade themselves that roasting, however painful, is good for them, and return, from what should be a period of renewal of health and vigour, irritable, enervated, and disappointed.

There are many other parts of the address which deserve careful study, especially by those—and they include nearly every practising member of our profession—who are asked to advise the place in which an invalid or a convalescent can best get what only a change of environment can give. It is certain that the present craving for noise and excitement will pass, and that the reaction will greatly favour those resorts which have preserved their individuality and have not become mere seaside replicas of busy cities. Dr. Watson Smith is no perfervid nationalist; he realizes that there are persons who should be prescribed that complete change of environment which can only be got abroad, but he rightly points out what a wealth and variety of resorts we have at home, in no way inferior to those on the Continent. His suggestion that this great national asset (largely undeveloped, as the Minister of Health recently said) should be cultivated and promoted by public authorities, is well worthy of the attention of our profession, from which the impetus should come; and the same remark applies to his demand for more convalescent homes for all classes of the community.

The President's graceful tribute to his predecessor in 1891, Dr. Roberts Thomson, will be welcomed not only by the older citizens of the town for which he did so much, but by those senior members of the British

JULY 28, 1934]

COMPILATION OF PHARMACOPOEIAS

[THE BRITISH
MEDICAL JOURNAL] 173

Medical Association who remember him both as a dignified President of the Association and as a devoted and very efficient Chairman of Council. We trust it will not be considered an impertinence if we supply two omissions in an admirable address. In the enumeration of the things which contribute to the happiness of the mind which all well-ordered health resorts should supply the President surprisingly did not mention music. Bournemouth has a very honourable record in this matter, for during many years, at great expense, it has created and generously supplied real music which has been a source of happiness to large numbers of its grateful visitors. And is it not desirable that at this time it should again be put on record that it was at Bournemouth that a celebrated seeker after health, Robert Louis Stevenson, wrote one of the finest tributes ever offered to our profession in the dedication of his volume *Underwoods*?

COMPILATION OF PHARMACOPOEIAS

The chairman's address to the British Pharmaceutical Congress this year, which was delivered by Dr. C. H. Hampshire, contains a very interesting comparison of the national pharmacopoeias of European countries. The occasion was opportune because no fewer than eight countries, including our own, have published new pharmacopoeias during the last four years. Dr. Hampshire pointed out that the character of pharmacopoeias has altered essentially during the last two centuries: whereas they were originally collections of recipes, to-day they are books of standards. The contents of pharmacopoeias also have changed fundamentally during the last half-century, since the number of crude organic drugs or galenicals has decreased, while synthetic drugs, hormones, and sera have been introduced in steadily increasing numbers. The aim of a modern pharmacopoeia was stated to be to "reflect the best knowledge of the time in the medical, pharmaceutical, and chemical fields." This definition will meet with general approval, but the attainment of this standard is beset with certain difficulties.

A consideration of the history of drugs shows extraordinary waves of fashion in their mode of use and their popularity, and the problem is how to keep abreast of modern methods and yet to avoid introduction of substances which enjoy an ephemeral popularity and then fall into disuse. Fortunately violent revolutions in therapeutics are becoming less frequent because the subject is more and more based upon scientific evidence instead of upon authoritative statements. On the other hand, the technical and literary efforts of pharmaceutical manufacturers have introduced a new disturbing element. It is, however, satisfactory to learn that there is a very fair measure of agreement between different countries in regard to the compilation of pharmacopoeias. An interesting comparative analysis of the eight recent national pharmacopoeias presented by Dr. Hampshire shows that although some countries

are more conservative than others, yet on the whole the pharmacopoeias have been compiled on fairly uniform principles. Curiously enough the Swiss Pharmacopoeia contains the largest number of monographs (1,148 as compared with 587 in the *British Pharmacopoeia* of 1932), and also contains a high proportion of crude vegetable drugs, galenicals, and compounded preparations. On the other hand, the Spanish Pharmacopoeia is mentioned as being one of the most satisfying and instructive of the modern pharmacopoeias. This contrast is remarkable, since Switzerland is the special home of the synthetic drug trade. The virtual correspondence between modern pharmacopoeias naturally raises the question of the practicability of an international pharmacopoeia. This project was started in 1874, and a pharmacopoeia was actually prepared in 1885, but the book never came into use in any country, and was forgotten. Since then attention has been concentrated on obtaining international uniformity regarding the more potent drugs, and a large measure of success has been attained by the two international congresses, in 1902 and 1925. Unfortunately, however, no permanent machinery has been evolved. It was hoped that the League of Nations would take over such work, but this has not yet been arranged.

The substantial agreement that occurs in practice between the pharmacopoeias of different countries is a gratifying proof of the international character of modern medical science. Many and obvious difficulties stand in the way of establishing an international pharmacopoeia, but there is no doubt that unification of standards would be greatly accelerated if there were any form of permanent international organization which interested itself in this work. The international conferences on vitamin standardization have proved how much can be accomplished in the unification of standards, and we may hope that before very long the Health Organization of the League of Nations will find it possible to set up a permanent organization to encourage and facilitate international agreements regarding pharmacopoeial preparations in general.

SIR ROBERT MUIR

The current issue of the *Journal of Pathology and Bacteriology* (July, 1934, xxxix, No. 1) is published in honour of Sir Robert Muir, on the occasion of his seventieth birthday, and is composed entirely of papers by his former pupils. This admirably conceived tribute gained even further by the circumstances of its appearance, for every member of the Pathological Society received his copy on July 5th, the day of this anniversary, and we understand that for Sir Robert Muir himself its arrival on his birthday morning was the first intimation that the next issue of this journal was to contain any unusual feature. The career which this volume is designed to honour is one without any exact parallel among British pathologists in this generation. During his thirty-five years' tenure of the chair of pathology at Glasgow Sir Robert Muir has raised this

school to a commanding position. He has himself made notable contributions to knowledge, particularly in studies of immunity and of the metabolism of haemoglobin and bile pigments. His influence has contributed largely to securing due recognition and independence for the study of pathology, and to according it a proper place in the medical curriculum. But it is as a teacher that his greatest work has been done. The surest tribute that can be paid to a teacher in any branch of medicine is that his pupils, after graduation, should return to that branch as their life's work. If they are then encouraged and inspired to embark on the difficulties of original research and an academic career, the achievement on the part of the man shaping their destinies is greater still. It is to this that the school of pathology in Glasgow owes its present unequalled reputation. The pupils of Sir Robert Muir have carried the influence of Glasgow far and wide, and they are to be found as teachers of pathology in many places. It is because the careers of his pupils represent their teacher's highest achievement that the present tribute to him is so singularly appropriate. Of the authors of the twenty papers which it contains, ten are occupants of chairs of pathology or bacteriology in medical schools in Great Britain. We congratulate the editors of the *Journal of Pathology and Bacteriology* on a happy epitome of one of the great careers of this generation, and wish Sir Robert Muir many more years in which to enjoy the honoured position he has reached.

"THE BOOK OF BOURNEMOUTH"

Every member attending the one hundred and second Annual Meeting of the British Medical Association this week has received a copy of the *Book of Bournemouth*,

edited by the President-Elect, Dr. S. Watson Smith. This is a very handsome and well-produced volume, reflecting great credit on the editor and his able fellow contributors, and on the publishers, Messrs. Pardy and Son of Bournemouth. For many years past it has been the custom to publish a book on the town in which the Association meets, and all who turn its pages will agree that the *Book of Bournemouth* is one of the best of a long series. For this result due praise must be given to the Bournemouth County Borough Council, which has generously borne the cost of production. The blue binding, with gold crest and lettering, is most attractive, and within the covers are delightful maps drawn by Dr. E. G. R. Grant. The frontispiece is a portrait of the President-Elect, and this and the many other illustrations form a notable feature of the book. Indeed, all the photographs, sketches, and old prints are admirably reproduced, so that apart from the interest and literary merit of the letterpress this volume will be treasured as a memento of the Annual Meeting of 1934. "Each article," writes Dr. Watson Smith in his preface, "is

an individual piece of descriptive writing; together, the various essays picture one of the most naturally beautiful and historically interesting parts of England." Each of the twenty-two essays, as well as the "index of places of historical interest and natural beauty in the neighbourhood," deserves individual notice, but space permits brief mention of only a few. The geology, geography, and natural history of the Bournemouth area are attractively described by local experts, and the editor himself writes on climatology, on hospitals and benevolent institutions, and on Bournemouth in 1934. The history of "the queen of watering-places" is sketched by the borough librarian, and the development of Bournemouth as a health resort by the medical officer of health, Dr. H. Gordon Smith. Mr. Herbert Druitt contributes learned notes on early Christchurch, and Dr. Le Fleming conveys the spirit of Wimborne within less than two pages. Mr. Clive Holland writes on the literary associations of Hampshire and Dorset, and Mr. Stanton on the place names of the two counties. Other articles are devoted to Cranborne and Cranborne Chase, to Poole past and present, to the New Forest and the Hampshire Avon, and to the Purbecks and the lakeland of Dorset. Altogether a charming book, of much historical interest.

ANNUAL REPRESENTATIVE MEETING

Gorgeous skies and inviting beach were not able to seduce the representatives from their hard labour in the Town Hall at Bournemouth. The Representative Body sat more closely to its business than at any meeting of recent years, its programme being a full nine-hour day, with two very brief intervals. Yet in spite of this full pressure, the state of the agenda on Saturday evening caused the chairman some anxiety. Whenever a speaker had begged an extension of time this had readily been accorded by the meeting, until at length the chairman, Dr. Le Fleming, said that he would be compelled, in the interests of the important matters yet to come forward, to overrule such generosity. It can safely be claimed that no other professional or technical body at its annual conference allows itself so little relaxation or sits so continuously to its task. Moreover, some of the best debating this year has taken place during the later stages of the meeting, when passing from preliminary and domestic matters to subjects of wider concern, such as medical education and public health. Indeed, one representative was so exhilarated that he proposed that the Representative Meeting should sit on Sunday, a proposal which found no favour. At the Representatives' Dinner the chairman remarked on the fact that although there were nearly a hundred representatives attending the meeting for the first time, very few fresh voices so far had been heard. It was certainly true that the honours of debate remained with the seniors, and in particular with a former Chairman of the Representative Body, Dr. Hawthorne, who won fresh laurels for platform mastery. Whether he appeared as Chairman of the Ethical Committee, pressing recommendations in face of not a little dissent, or, having doffed that mantle, as the principal dissenter against other recommendations of the Ethical Committee, he was equally persuasive as an orator and formidable as an opponent. As a little example of his readiness in repartee one

July 28, 1934]

THE BOURNEMOUTH MEETING

incident which convulsed the meeting may be quoted. He was in the midst of a speech when he heard an ejaculation below him which he at first took to be a question or challenge to his statements. Realizing after a moment that what was taking place had nothing to do with the debate, he remarked, in all good humour, "Oh, I am sorry to have intruded into a private conversation!" The impression remains that, with Dr. Hawthorne's dialectical skill, Sir Henry Brackenbury's logic, and Sir Robert Bolam's incisive argument, they have been days of triumph for the elders. With this meeting Dr. Le Fleming reached the end of his period of office, and we may be allowed to add a word to the many said at Bournemouth in praise of his admirable conduct of the business of the Representative Body during the past three years.

THE REPRESENTATIVE BODY RELAXES

It is perhaps a truism to-day to say that each Annual Meeting is unique. But this quality of uniqueness depends as much as anything else upon the locality of the meeting. The doctor is always a good host because he understands the psychotherapeutic value of benevolence, and to his own colleagues he gives the outward semblances of benevolence—good food and wine, good company and entertainment—without stint and with both hands. At the end of a hard Saturday's work in the Annual Representative Meeting, during which chiropody had its full share of attention, he forgot the penalties of dancing in ill-fitting shoes in the pleasant entertainments offered by the Bournemouth Medical Society at the Burlington Hotel, Boscombe, and by the British Dental Association at Branksome Towers Hotel. If corns and bunions were to develop, there was always the comforting assurance that his fellow representatives, who had refused a measure of recognition for the chiropodists, would offer him expert advice and treatment. On the Sunday the civic authorities of Poole showed that in the matter of hospitality they could meet the medical profession on its own ground, and the representatives and their wives enjoyed to the full the delightful excursion round Poole Harbour arranged by the Mayor and the Corporation of Poole. Some 400 guests went by motor-coach by way of the lovely Canford Cliffs—pausing to inspect the Sandbanks Bathing Pavilion—to the municipal buildings of Poole, where they were welcomed by the Mayor, Councillor W. C. J. Shortt, J.P. After a lunch, at which both appetite and calories were admirably provided for, the Mayor toasted the British Medical Association in a brief and gracious speech. Extending them that the Romans had used its waterways some 2,000 years ago, and that since then it had played an important part in naval and military history. Replying to the toast the Medical Secretary, Dr. G. C. Anderson, having classified succinctly—and, to judge from the laughter, not inaccurately—the various ways in which the Annual representatives attended to the business of the Annual Representative Meeting, paid a handsome tribute to the *Book of Bournemouth*. After Dr. Anderson had concluded his speech by expressing thanks for the hospitality of the Corporation of Poole, Dr. Le Fleming proposed the toast of "The Borough." Poole, he

said, had suffered many invasions in the course of its history, but this visit of the British Medical Association must be counted as one of its major incursions.

INCREASED MORTALITY FROM DIABETES

A statistical study of diabetes mellitus has recently been published in the *American Journal of Medical Sciences*,¹ in which the physician Joslin co-operates with two statisticians from the Metropolitan Life Insurance Company. In this way a really important and balanced picture of the incidence and mortality of diabetes has been produced, essentially based on a study of American and international statistics, but leavened and weighed by the experience of matured clinical judgement. The conclusion to be drawn is clear from their facts—namely, that diabetic mortality is increasing all over the civilized world. The authors offer no explanation of the phenomenon. The first article, on characteristics and trends of diabetes mortality, clearly reveals how diabetes is becoming more and more prevalent throughout the world. As a cause of death in the United States registration area it has advanced from twenty-seventh in rank in 1900 to ninth in 1932. In practically every European country there is a comparable increase, and countries of European descent, like New Zealand and Australia, share in it. There is a clear tendency in Europe for Teutonic peoples to suffer more frequently from diabetes than the Latins. In England the recent death rate are the highest on record, that of 1931 being 29.5 per cent. higher than in 1925, and 45 per cent. higher than in 1920. This rise in the registered diabetic death rate is nothing new, and has been progressing fairly uniformly since at least 1900. It shows two periods of war, and, secondly, during the early years after the general use of insulin. But of late years, in which the employment of insulin has been more efficient and widespread, the mortality rate has been higher than ever. Does this mean that insulin is at least statistically ineffective, or is there some other explanation of the mounting death rate? The authors supply further statistics of interest and importance on these questions. The increase in diabetic mortality is only in the latter decades of life, from 45 years onwards. Below this age the death rate has actually declined. It is certain that the previously most fatal and quickly progressive types of diabetes—in children and in early adult life—have been definitely checked and diminished by insulin. The death rate in young diabetics has fallen by more than half. Still more striking is the difference in sex mortality. Some twenty years ago more men died from diabetes than women, and the death rate in males has risen very little. In women under 35 there is also no recent increase, but in later life a very substantial rise has taken place, until at the age of 65 the number of female deaths is twice that of males. This is true in America of both white and coloured people, and in England and in most of North-West Europe. As regards countries, America has been in the most "civilized" countries. America where trustworthy statistical evidence is available, this indicates that the greatest increase in diabetic deaths

¹ *Amer. Journ. Med. Sci.*, December, 1933, p. 753, and April, 1934, p. 433.

leads the race, and on the present figures it is computed that over 2.5 million persons, or 2.1 per cent. of the population, will eventually succumb to diabetes. It is again apparent that the death rate among Jews is much higher than among Gentiles. But this is true only of ages over 55; in the young there is no difference between the two groups. It is interesting to note that in Ireland the diabetic death rate is low, whereas in the American Irish it is unusually high: the standard of living of the latter is better, and an unusually large proportion are engaged in the liquor trade. The statistics on occupational incidence are clear and interesting. The labourer and the manual worker have the lowest death rate; that of the professional man and the mental worker is much higher; and the list is headed by persons occupied in the distribution of food and drink. The mortality of hotel keepers and publicans is the greatest recorded for any occupational group (England and Wales). A discussion by the authors on the factors influencing the incidence of diabetes will be awaited with interest.

A NEW DIAGNOSTIC TEST FOR CANCER

Laboratory tests with which it is claimed that cancer can be diagnosed are usually performed with the patient's blood. That proposed by Aron¹ employs the urine, a material which was chosen on the assumption that the abnormal metabolism, or alternatively the degeneration of malignant tissue, should liberate bodies which may be excreted by the kidney. The indicator chosen for demonstrating the presence of these hypothetical bodies is the adrenal gland of the rabbit, the argument here being that this organ is highly susceptible to toxic influences of many kinds. The precipitate obtained when about a litre of urine is treated with alcohol is redissolved and injected into a rabbit in divided doses on several successive days, the animal being killed on the day following the last of these. The "cancer reaction" consists in the partial or complete disappearance of lipoids from the cortex of the adrenal, and was obtained in all but two of a series of cases of malignant disease when a sufficient amount of urine was used for the test; earlier attempts with smaller volumes were not always successful. Control urines from normal individuals, pregnant women, and patients with a variety of other diseases gave negative results. As a diagnostic test it would appear from this information that the procedure is of some service, though one would like to know the extent of the growth which must exist before the test becomes positive: a method which is only reliable in the advanced stages of cancer can be of little value. Since urine is so much more readily obtainable in large amounts than blood, it is perhaps also permissible to suggest that some attempt might be made to fractionate the material obtained from it, with the object not only of concentrating the active substance in it but of gaining some idea of its nature. Some such extension of Aron's observations seems all the more necessary because he goes altogether beyond proposing what is, after all, a purely empirical test. Apparently the serum of a rabbit previously treated with urine from a case of cancer will prevent the cancer reaction in the adrenal of a second rabbit treated with the same urine. This pro-

tective effect can also be exerted by the serum of the patient from whom the urine is obtained. These observations, and the (tentative) use of the term "antibody" in connexion with them, place the whole matter on an altogether different footing, and it is clearly necessary to inquire further into the basis of these phenomena. An early step which we think should be taken is to study the nature and mechanism of the change in the adrenal cortex, and the possibility of eliciting it with other reagents. There appears to be no reason why any material from a patient suffering from malignant disease should have this particular type of effect, and, assuming that Aron's observations can be elucidated in this sense as well as verified, the results might be of interest in directions other than that to which his work owes its origin.

CO-OPERATION IN MEDICAL EDUCATION

Our readers will be interested to learn that the Governing Bodies of St. Bartholomew's Hospital Medical College, St. Thomas's Hospital Medical School, and Guy's Hospital Medical School have decided to establish a closer co-operation for the advancement of medical education. The medical schools of London have grown rapidly during the last century and a half. They originated in a system of apprenticeship, under which the students became attached to individual members of the staffs of the various hospitals. Later this system came to an end, and organized schools were established. Early in the present century these schools became constituent colleges of the University of London. The range of medical education has now become so wide, and the subjects included in the training of a doctor so complex, that the problems of the teachers are growing more and more difficult. It is to meet this difficulty that the co-operation between the three schools mentioned has come about. The first steps must necessarily be slow. An executive council has been formed, consisting of the dean and four other members of the teaching staff of each school. Meetings, at which subjects of educational importance will be discussed, will be held throughout the year. The decisions reached will be referred to each school for consideration and such action as may be agreed. In order that the co-operation may be as close as possible the dean of each school will be invited to attend the council meetings of the other two schools when subjects of general interest are being reviewed. A further step has been taken. Certain courses of study are being organized for which it is difficult to cater in an individual school, but which can be arranged without difficulty when the students of more than one school will benefit. Further, the students of each school will be permitted, under an arranged scheme, to avail themselves of the clinical facilities of the other schools. In order to allow the scheme to develop gradually, in some instances the arrangements for an interchange of clinical teaching will be restricted for an initial period to St. Bartholomew's and St. Thomas's. When, after some preliminary experience, the organization has become stabilized, similar facilities will be extended to students of Guy's. It is hoped that co-operation on these lines will be of great value to the cause of medical education, and it is felt that the wider outlook thus made possible for the students must be of real benefit to them.

MEDICAL JOURNAL 177

PROLONGATION OF PREGNANCY

Several workers have shown that it is possible to induce ovulation in the rabbit by a single injection of the anterior pituitary substance extracted from the urine of pregnant women. F. F. Snyder¹ has recently reported that ovulation may be caused in this animal in a similar manner during pregnancy. By injecting intravenously into rabbits 40 R.U. per kilo of body weight of antuitrin-S on the twenty-fourth to the twenty-sixth day of pregnancy, it was found possible in the majority of cases to delay parturition until fifteen days after the date of the injection. The foetuses remained alive for three days beyond the normal period of gestation and became post-mature. Their death did not, however, lead to the onset of labour, which was delayed until the end of the life-span of the induced corpus luteum. In some cases the foetuses were retained for several months, and this phenomenon was invariably associated with damage to the uterus caused by their gross over-development. Pituitrin injected at term failed to induce parturition, although 1,000 times the dosage normally follows coitus, employed. In the rabbit ovulation follows coitus, except during pregnancy. In this series of animals ovulation did not follow coitus until fourteen days had elapsed after the injection of antuitrin-S. The author concludes that in rabbits the onset of parturition is governed by the corpus luteum. In women the corpus luteum commences to degenerate during the fifth month of pregnancy. The significance of these results can best be appreciated if the question, Why does an animal go into labour after a fixed interval of time following conception? be changed to, Why does a hollow muscular organ like the uterus retain the products of conception? In the rabbit the corpus luteum hinders expulsion of the ovum, and in every other animal some inhibitory influence must be at work.

"BRITISH JOURNAL OF TUBERCULOSIS"

Dr. L. S. T. Burrell has succeeded Dr. T. N. Kelynack as editor of the *British Journal of Tuberculosis*. This periodical came into being in January, 1907, and has been conducted ever since by Dr. Kelynack. In the past it has endeavoured to cater for the requirements of lay as well as medical students of this disease, providing articles and discussions on sociological topics as well as on medical subjects. The new editor has had a distinguished career, having been physician to the Brompton, Royal Free, and Royal National Hospitals; he is also consultant physician to the Papworth Village Settlement, Benenden and Midhurst Sanatoria, and an examiner in medicine for the University of Cambridge and the Conjoint Board. Dr. Burrell brings to his new task, therefore, a wide outlook, as well as an exceptionally deep knowledge of tuberculosis in its various manifestations. It is announced that among new features to be introduced into the next volume of the journal, the first issue of which will appear in January, 1935, is the inauguration of discussions of problems of special importance and controversial character. Topics under consideration for this purpose include: the endogenous or exogenous nature of adult infection; why surgical tuberculosis is more common

in the child and the pulmonary form in the adult; the tendency in only some cases for the development of laryngitis and enteritis; why the most virulent type of pulmonary tuberculosis is seen in women during child-bearing age; and cognate veterinary questions. Attempts are to be made to encourage research, and readers are invited not only to send letters for publication, but to suggest problems which might be tackled. Another new feature which will be introduced into each number is a consultation. A hypothetical case will be described, the past history, treatment, present physical signs, and symptoms being given in detail, followed by a discussion of the prognosis and future treatment. Surgical tuberculosis will receive special consideration. The July issue contains a survey of tuberculosis in Wales, with special reference to certain prevailing adverse influences. This is followed by a general review of influences adverse to tuberculous patients, based on an investigation carried out in the county borough of West Bromwich, and bringing into clear relief the importance of the problem of locality in delaying the start of treatment and militating against subsequent maintenance of health. There are also notes on Alpine climate in connexion with laryngeal tuberculosis and a report on gold treatment of the pulmonary form. Dr. Kelynack, to whom the *British Journal of Tuberculosis* owes so much, is continuing his association with it as consulting editor.

MEDICAL INSURANCE AGENCY

A meeting of the committee of management of the Medical Insurance Agency Limited (by Guarantee) was held at the House of the British Medical Association on July 12th, when the report of the Agency's work during the year 1933 and the corresponding balance sheet were adopted. The accounts showed satisfactory progress in the business transacted on behalf of members of the medical profession during the year. In life assurance—an important part of the Agency's work—the results attained in 1932 were surpassed, while in motor car insurance the position was maintained, notwithstanding heavy competition. Fire, household, and miscellaneous insurances have kept at a steady level, both on renewals and in new business. Of the available surplus of £3,297 the sum of £2,937 10s. was distributed to medical charities, as set out below, making a total contribution to the cause of medical benevolence, since the foundation of the Medical Insurance Agency twenty-seven years ago, of £35,625.

¹ Bull. Johns Hopkins Hosp., 1934, liv, 1.

ROBERT JONES NATIONAL MEMORIAL

MEETING AT MANSION HOUSE

A meeting, presided over by the LORD MAYOR, who was accompanied by the Lady Mayoress and attended by the Sheriffs, was held at the Mansion House, London, on July 18th, in support of the Robert Jones National Memorial, inaugurated to perpetuate the life-work of the creator of modern orthopaedic surgery. The memorial proposes to establish (1) a Robert Jones professorship in the Royal College of Surgeons of England, (2) a Robert Jones travelling fellowship, to be elected alternately by the Royal College of Surgeons and (jointly) by the University of Liverpool and the Liverpool Medical Institution, and (3) a Robert Jones national trust, to ensure financial aid for orthopaedic centres or institutions, as and when most needed. The office of the National Memorial is at Quadrant House, 55, Pall Mall, S.W.1, and the appeal secretary is Mr. Charles Steuart.

Messages in support of the appeal were read from the Duchess of York, the patron, the Earl of Derby, the president, and the following among other vice-presidents: the Earl of Athlone, Mr. Stanley Baldwin, Lord and Lady Gladstone, the Earl of Lonsdale, Viscount Leverhulme, and Sir William Wheeler.

LORD MOYNIHAN, chairman of the executive committee of the memorial, said that he was voicing the feeling of the whole medical profession that a national memorial should be created to perpetuate the name and achievements of Robert Jones. His services to humanity were of outstanding merit, otherwise a merely local and temporary reminder would have been adequate. The gifts of Robert Jones not only to the science of surgery but to the art of surgery had been of a character that had surely rendered his name and work immortal. Immortality attached only to the things of the spirit, and it was the gift of Robert Jones to the spirit of surgery, and in particular to that very considerable—perhaps most important—department of it known as orthopaedic surgery, that the national memorial was designed to commemorate. Robert Jones's services throughout the war, when he was—perhaps not very easily—appointed Inspector of Military Orthopaedics, A.M.S., were familiar to everyone. He was one of the two great scientific heroes of the war, and it was the barest truth to say that hundreds of thousands of men owed not only their recovery but their restoration to physical health to the skill which he was able directly to exercise.

"The great thing about a member of my profession," Lord Moynihan continued, "is not his immediate work, but the craft he teaches, the spirit he inspires among those who come after. The lessons taught by Robert Jones throughout the war are now part of the heritage of surgeons all over the world. I may arrogate to myself for the moment a wider responsibility, and in the name of my colleagues across the Atlantic say that they will ever bear the name of Robert Jones in proudest remembrance. He was, in a sense, one of them as he was one of us. His work will go forward in every clinic in the world. There are a few men in my profession for whom we may claim immortality—Harvey, and Hunter, and Lister, the greatest of all. But among those whose names are written in letters of everlasting gold that of Robert Jones will certainly find a place. For the crippled children it was he who opened the gates of mercy and of relief."

THE DUCHESS OF ATHOLL, M.P., spoke of the pathos of crippleddom. Although the Royal National Orthopaedic Hospital was founded nearly a hundred years ago, she believed that with the advent of Robert Jones came a new stimulus and the beginning of an enormous development. She remembered well the first time she ever heard of him. It was a year or two before the war, and she recalled the wonder and enthusiasm with which a sister at some centre where he visited the children spoke of his work and of the cures he had been able to bring about. But in those days his work was scarcely known outside the medical profession, and his county scheme existed only in Shropshire, the pioneer county in that respect. When the war came it was a very different story, and

the tragic need for the development and extension of his work became evident. She was proud to think that for a year or two she was commandant at a tiny outpost of the hospitals embracing 33,000 beds, of which Robert Jones was the head and the inspiration. After the war schemes were established in one county after another, generally taking the form of a central hospital building, with clinics in various parts of the county, which clinics were visited from time to time by an orthopaedic surgeon and a trained nurse to see the children who had been returned to their homes from the central hospital and adjust appliances or prescribe massage as might be necessary. Of the proposals for the form of the memorial she welcomed most of all the national trust, out of which would be furnished financial help to the many counties in England and the many more in Scotland, which had no scheme.

SIR JOHN MARTIN-HARVEY, who also spoke in support of the appeal, mentioned some personal aspects of Robert Jones—his smile which was so reassuring to his child patients, his great kindness, and his skill which amounted to genius. When the idea of the first military orthopaedic hospital occurred to him he went to the higher command, and on being asked how many beds he wanted, said, modestly, about 250. Before the war was over Sir Robert Jones and the surgeons working with him and under him were responsible for considerably more than a hundred times that number.

MR. EDWARD HUGHES, chairman of the Rhyl Urban District Council, promised the utmost effort on the part of Rhyl to honour and perpetuate the work of its most illustrious townsman. He mentioned that not only was Robert Jones a native of Rhyl, but that in the hospital there Dame Agnes Hunt, who was so closely associated with him in the work for the cripples, started her career as a pupil nurse.

SIR HAROLD FAWCUS proposed and Mr. ROWLEY BRISTOW seconded a vote of thanks to the Lord Mayor, who, in reply, spoke of his great satisfaction that the Mansion House should take part in furthering the appeal for national recognition, in the form he would have loved, of the work of this great benefactor of humanity.

BRITISH INDUSTRIES HOUSE

SECTION FOR DISPLAY OF HOSPITAL EQUIPMENT

On July 19th the Earl of Derby opened a Medical Centre at British Industries House, Marble Arch, London. The purpose of British Industries House, for the development of Empire trade, has already been described in these pages. The Medical Section includes a complete hospital, occupying 10,000 sq. ft. of floor space, with a 12-bed ward, two operating theatres, a clinical laboratory, an anaesthetic department, sisters' rooms, and the usual accessories. The equipment is complete down to the semicircular sun balcony, the special window glass, the shadowless operating lamp, the taps which turn at the touch of the elbow, the instrument sterilizer, and, in the clinical laboratory, the standard bench and fume cupboard, the balances, calorimeters, centrifuges, and the general material for bacteriological and clinical work. What is claimed to be the most up-to-date hospital in the world is unique in one respect—that it has no patients. It is intended to afford to those interested in the purchase of hospital equipment the opportunity of inspecting modern furnishings and other commodities under one roof instead of having to visit scattered centres of manufacture. The hospital has been constructed from the plans of the architects (Adams, Holden, and Pearson) who are responsible for the new Westminster Hospital. In addition to the hospital there is in the Medical Section a wide range of British-made requisites for medical and surgical work, as well as articles needed on the lay side of hospital maintenance.

At the opening ceremony, which was attended by several hundreds of people, the chair was taken by Mr. H. M. TROUNCER, the chairman of the directors, and among those on the platform were Lord Dawson of Penn, Sir

Humphry Rolleston, Sir Holburt Waring, Sir Crisp English, Dr. E. P. Poulton, and Dr. Alfred Cox, who is chairman of the Advisory Council of the Medical Section.

The EARL of ELGIN briefly described the purposes of British Industries House in general and of the Medical Section in particular. The house itself, he said, consisted of three departments: (1) publicity and propaganda, (2) exhibition and advertisement of industry, and (3) club and meeting place in which the buyers of the world could be put in contact with the Empire manufacturers. The institution would serve as a clearing-house for inquiries and demands. Only a few days after the negotiations for the section took shape an inquiry was received from an authority which wished to set up a hospital as to where a full range of the necessary equipment was to be seen. The authority could only be informed that it was hoped in course of time that this would be available at the Marble Arch, but it was not to be found elsewhere at present. It was afterwards discovered that the inquirer was charged with the disposal of a contract amounting to about £25,000. In addition to the hospital described above, the Medical Section included showcases and show-rooms with a wide range of drugs and instruments.

The EARL of DERBY said that the organization appealed to him in the first instance as the head of a travel association, because he was sure that nine-tenths of the people who came from abroad to England for pleasure could be induced, if opportunity offered, to do business here as well. He felt that the excellence of home products was not appreciated by many, including those concerned with hospital provision. When it came to a question of ministering to the sick and suffering they must always give them the very best that could be obtained, independently of the country from which it came, but the object of the present exhibition was to suggest that although many of these articles had hitherto been obtained from abroad they could as a matter of fact be obtained in this country equally cheaply and of equal merit. Lord Derby went on to say that he had been connected, more or less as a figurehead, with many hospitals, but years ago he had a closer connexion with the London Hospital, and he knew from experience how difficult it was for anybody who desired to equip a department of that hospital to know exactly where to go to get any particular commodity. He felt that the new department would be of the greatest assistance to all concerned in hospital management, and he had great pleasure in declaring the Medical Section open. The thanks of those concerned were expressed to Lord Derby by Mr. TROUNCER from the chair, and afterwards the guests were conducted by stewards to the hospital block and to the club and inspected the exhibits.

Sir Hilton Young, the Minister of Health, who was accompanied by representatives of the various departments concerned, received a deputation, on July 17th, from the British Association and the Institution of Civil Engineers. The object of the deputation was to invite the Government to give favourable consideration to the institution of a complete and systematic survey of the water resources of the country, a subject on which a committee of the British Association had recently published a report. The deputation suggested that the existing records both of surface water, including river run-off, and of underground supplies were very incomplete. It urged that systematic records comparable with those of rainfall were much to be desired and that a national survey was necessary in order to obtain statistics of this nature. The Minister, in reply, thanked the British Association and the Institution of Civil Engineers for the consideration which had been given to the matter, and said that their suggestions would receive the most careful consideration of the Government. Sources of information were available through the Ministry of Health, the Geological Survey, and the Catchment Boards. It was for consideration whether the progress which was to be desired in the collection of statistics could not best be achieved by improving the existing means of gauging the flow of rivers and by improvements in the method of collecting and presenting returns.

Scotland

New Glasgow Professor

The vacancy in the chair of midwifery at the University of Glasgow, created by the retirement of Professor J. M. Munro Kerr, has been filled by the appointment of Samuel James Cameron, M.B., F.R.F.P.S.Glas. The appointment lies with the Crown, and the King has approved of this selection. Professor Cameron is the son of the late Professor Murdoch Cameron, who occupied the same chair for many years until he retired in 1927. He is a graduate of Glasgow University, and has held numerous obstetric appointments in that city, being obstetric surgeon and gynaecologist to the Glasgow Maternity Hospital, and consulting obstetric surgeon to the Lanark County Council's Hospital at Bellshill and to the Motherwell Maternity Hospital, as well as consulting obstetrician to the Maternity Hospital in Perth. He is one of the gynaecologists to the Western Infirmary, Glasgow, and examiner in obstetrics to the University of St. Andrews. Professor Cameron has published the results of much research work in *The Manual of Gynaecology*, which went into a third edition in 1928, and in numerous contributions to the medical journals.

Edinburgh Medical Graduation

At the medical graduation at Edinburgh University, on July 18th, Principal Sir Thomas Holland, who presided, handed the Cameron prize in practical therapeutics to Emeritus Professor Sir E. Sharpey-Schafer, in recognition of the advances in therapeutics that had arisen from his discoveries in endocrinology. Professor A. J. Clark, in his address to the 128 new graduates whom he had presented for the degree of M.B., Ch.B., discussed the rapid development of modern medical science and its influence on the future of the profession. It had been their privilege, he said, to study medicine during a period of intensive growth, but this had carried with it the penalty of receiving a medical education which was somewhat of a makeshift, hurriedly adjusted to a rapidly changing body of knowledge. It was to be hoped that medical science would make as great advances in the immediate future as it had done in the recent past, and that the necessity for post-graduate education would be adequately realized. During the last century the death rate had fallen steadily, and the popular standards of health had risen in a remarkable fashion. The public was beginning to expect the medical profession to teach it how to maintain a condition of physical fitness, and the prevention of disease was becoming one of the chief functions of the doctor. This tended to make the practice of medicine both more difficult and more interesting. The change in the nature of the services demanded by the public increased the importance of treatment, since diseases would be seen more frequently at an early and curable stage. It was possible to estimate, with a fair degree of certainty, the composition of the population ten or twenty years hence, and it was clear that that population would be one with relatively fewer children than in the past, and with an ever-increasing proportion of old people. The fewer children there were the more precious would they be, and the more dependent would be their parents upon professional advice. On the other hand, the steady rise in the number of persons over 65 was bound to have a marked effect on medical practice, for the human body, as the result of the wear and tear of life, would require increasing attention in old age. The degree of Doctor of Medicine was awarded to sixteen graduates, and that of Master of Surgery to one. Three candidates received the degree of Doctor of Philosophy in medicine, and one in

180 JULY 28, 1934]

SCOTLAND

science; while eight diplomas in public health, five in tropical medicine, one in psychiatry, two in radiology, and three in tropical veterinary medicine were awarded.

Research in Animal Diseases

At the annual general meeting of the Animal Diseases Research Association, held at Moredun Institute, Gilmerston, Edinburgh, Dr. J. Russell Greig, director of the institute, said that the results obtained from the investigation of animal disease were important to those who studied the diseases of man, and there was close collaboration between the medical and the veterinary research worker on the staff and the committee of the institute. During the short time that the institute had functioned control had been obtained over such diseases as lamb dysentery, braxy, louping-ill, milk fever, iron deficiency, pine, and lactation tetany. The institute had a wide programme of research, but promising lines of work had often temporarily to be laid aside, because other urgent problems arose which required immediate study. Among the latter was grass-sickness, which claimed the whole of the institute for a certain period of the year when acute cases occurred. This disorder must be regarded as a national scourge, and it was proposed to allocate to it the whole time of a trained worker. The institute needed more staff and further accommodation. An adequate extension would involve a capital expenditure of £10,000, which might be regarded as a small sum in relation to the losses suffered by agriculture through animal disease and death.

Pathology in Scottish Mental Hospitals

Changes have been made in the administration of the Scottish Mental Hospitals' Pathological Scheme, closer association having been effected with the University of Edinburgh, and especially with the departments concerned with the teaching of clinical psychiatry, neurology, and clinical medicine. Accordingly, Dr. A. Murray Drennan, who is professor of pathology in the University, became director of the scheme at the beginning of last year, and in the following October Dr. J. Henry Biggart was appointed pathologist. In the thirty-sixth report of the scheme, covering the years 1932 and 1933, Professor Drennan describes the working of the various specimens, a new method of filing and indexing the collection of a permanent collection of slides, and case reports will be correlated. Eventually, various series of the different diseases affecting the brain will be obtained, and with the correlation of symptoms and pathological knowledge of provide an opportunity for increasing changes will cerebral function. A filing cabinet for demonstration slides for teaching purposes has been built up: as material accumulates a complete demonstration of the various cerebral lesions will become available. It has also been thought desirable to build up a few demonstration collections, which could be lent to those wishing to take examination for the diploma in psychiatry. A course of lectures and demonstrations on the pathology of the nervous system for the M.R.C.P. was begun last January. In the task of improving the teaching material in the laboratory the pathology departments at the University and the Royal Infirmary have co-operated effectively. Since last October thirty brains have been submitted to histological examination, several tumour specimens investigated, and necropsies performed in other institutions. Professor Drennan suggests that at least one necropsy should be undertaken in each mental hospital by the pathologist of the scheme, or, alternatively, that the various assistant medical officers of these hospitals should attend one or more necropsies at some centre so that the

technique should be thoroughly mastered by them. Research work is at present being conducted on the anterior and posterior lobes of the pituitary body and the hypothalamus; material is also being collected for study of the pathological basis of the Argyll Robertson pupil. Professor Drennan appeals for a constant supply of necropsy material from the various mental hospitals; with the present staff it would be possible to examine about 200 brains each year at the laboratory, and from this work various lines of further research would be indicated with later benefit to the clinician. Mental hospital staffs are therefore asked to supply full clinical accounts when sending such material for examination, and to make suggestions for investigations which would seem to be desirable. Assistance is promised to any medical officers in mental hospitals associated with the scheme who will make themselves responsible for the simple pathological work in these institutions. The hope is expressed that in time each mental hospital will have one of its staff interested and instructed in the pathological aspects of mental disease. There would thus be brought into being a group of workers in touch simultaneously with the clinical problems and the central laboratory of the scheme, and real co-ordinated research work could be undertaken.

Ireland

The Rotunda Hospital, Dublin

The annual report of the Rotunda Hospital for the year ending October 31st, 1933, is the last one to be issued by Dr. Bethel Solomons, whose seven years as resident Master have now terminated. His swan song, he writes, must needs be both glad and sad, yet he endorses the provision of Benjamin Mosse that there should be a series of years' rulership only, for thus it can be assured that fresh ideas shall be forthcoming periodically, and that no stagnation be allowed to creep in. During Dr. Solomons's term of Mastership there were nearly 4,000 more women admitted to the hospital than in the previous seven years. He believes this increase will continue in the future, and especially its nurses. In August, 1933, the then record number of 243 women were delivered, but this figure has since been exceeded. In the twelve months under review there were 2,650 admissions to the maternity side of the hospital, of whom 2,376 were delivered. The prenatal departments were particularly busy, and the need for a new out-patient department is more than urgent, both for the comfort of the patients and also for facility in teaching this highly important branch. The ampoule or capsule system of chloroform administration has been given careful trial, with very satisfactory results. Dr. Solomons's views about the danger of chloroform are well known. His considered opinion about the ampoule method is that it fills a want; that, although it can be given during the late first stage in labour, it seems to cause delay if administered then; and that it is convenient and apparently foolproof. In spite of this, he does not agree that it should be put into the hands of the unqualified—namely, midwives—without supervision. In a large number of cases analgesia in the first stage of labour was satisfactory with a mixture of hyoscine and sodium amylal. There were 132 stillbirths in the year, and twenty-eight of these foetuses were macerated. These figures are considered satisfactory, for of the 104 recent stillbirths no foetal heart beat was perceptible on admission in twenty-four, and thirty were toxæmic. The number of albuminuric patients was 549, as compared with 810 in the previous year, but it is hard to say how far this diminution may be due to better prenatal supervision.

There were ten possible eclamptics, but it is doubtful whether four of these should be thus described. Only three cases of severe vomiting classifiable as hyperemesis occurred; treatment by gastric lavage, starvation, colonic lavage, and rectal and intravenous glucose brought about successful results. There were eighteen cases of placenta praevia without mortality, bringing Dr. Solomons's series up to 138 with two deaths. He maintains that this condition, properly treated, should never be fatal. Only fourteen cases of inertia were recorded, although there were many other slow labours. Spontaneous labour occurred in six, and forceps were applied in eight cases. Caesarean section was never necessary. The treatment consisted of long hot vaginal douches, given twice daily if necessary, much watchfulness, and rest by means of hypnotics. Dr. Solomons repeats his precept that it is dangerous to give pituitary extract to this type of case in a teaching hospital. Of the thirty-one Caesarean sections performed without mortality the classical operation was employed five times, in three for absolute disproportion. The lower segment route was chosen on fourteen occasions; it is described as the ideal operation for the obstetrician who understands the mechanism of labour, and the pronounced semi-elliptical incision is regarded as the best type. There was no death from puerperal sepsis during the year. Dr. Solomons deprecates the wearing of masks in extern work in private houses, and even in hospitals, on the grounds that the unskilled, and even some of the skilled, may be led to overlook the important principles which favour a clean delivery. To the gynaecological wing there were 686 admissions during the year, operation being required in 533. Diathermy continues to be used with benefit in parametritis, but it is remarked that patients also get on very well with the old-fashioned treatment of vaginal douches and tampons of ichthyol in glycerin.

Vital Statistics for the Irish Free State

The birth rate for the first quarter of 1934 was 19.3 per 1,000, representing 14,538 births registered. This was 0.3 above the average of 19 for the first quarter of the five years 1929-33. For Dublin City the birth rate was 27; for Dun Laoghaire, 17.5; Cork, 21.9; Limerick, 25.7; and Waterford, 24.2. The corresponding birth rate for Northern Ireland was 20; for England and Wales, 15; and for Scotland, 18.7. The birth rate for Belfast was 24, for Londonderry, 26.4, for London, 13.3; for Glasgow, 19.7; and for Edinburgh, 16.6. The rate in respect of deaths registered (in number 11,634) was 15.4, being 2.5 below the average of 17.9 for the first quarter of the preceding five years. For Dublin City the death rate was 16.5, Dun Laoghaire, 19.1; Cork, 19.7; Limerick, 17, and Waterford, 15.2. In Northern Ireland the death rate for the quarter under review was 15.9 per 1,000; in England and Wales, 14.7, and in Scotland, 14.3. In Belfast the rate was 18.5, in Londonderry, 16.8; in London, 15.8; in Glasgow, 14.8, and in Edinburgh, 14.7. Deaths from the principal epidemic diseases afforded an annual rate of 0.5 per 1,000, which is 0.1 below the average for the first quarter of the five years 1929-33. The mortality from influenza was equivalent to a rate of 0.4 per 1,000, which is 0.7 below the average for the corresponding quarter of the preceding five years. The rate for deaths from all quarters from tuberculous diseases was 1.2 per 1,000, being 0.2 below the average rate for the first quarter of the preceding five years. Deaths from principal causes gave a rate of 4.8 per 1,000. Births registered comprised 19 for parturient women and 20.1 for still-born children, as compared with 1.2 and 1.4 for the first quarter of 1933. The infant mortality rate was 84, as against an average of 85 for the first quarter of the five years 1929-33.

CORRESPONDENCE

The Scottish Health Services

SIR.—The Scottish Committee deserves whole-hearted congratulation on the very able memorandum of evidence for submission to the Departmental Committee on Scottish Health Services, which was printed in the *Supplement* of July 7th. It is regrettable, however, that the memorandum was not submitted to meetings of Scottish Divisions for consideration, as had at one time been suggested.

The memorandum, I believe, represents very accurately the views of Scottish general practitioners in regard to many matters which have been occupying the attention of the profession in recent years. This is creditable alike to the general practitioner members of the committee and to the others. Other sections of the profession can present their views to the Departmental Committee through agencies that are representative solely of sectional interests—for example, the Royal Colleges representing consultants and the staffs of teaching hospitals, and the Society of Medical Officers of Health. One hopes, therefore, that the Scottish Committee will maintain general practitioner views as strongly as possible in the oral evidence to be submitted to the Departmental Committee.

The community in general and the medical profession in particular are confronted by an appalling increase of bureaucratizing tendencies, especially since the Local Government (Scotland) Act of 1929. These bureaucratizing tendencies have been responsible for many of the difficulties of the general practitioner, particularly in urban areas, and a recognition of this fact is the basis of much of the evidence in the Scottish Committee's memorandum.

Extensions and improvements in the health services of Scotland will involve an increase in the number of administrative and medical officials. The problem before the profession is how to safeguard the community and itself against bureaucratic encroachments. The presence of elected representatives of the profession on the Department of Health and on local public health committees would be such a safeguard.

Administrative convenience and uniformity appear to override in the official mind the truer interests of the community. All the infectious cases of a large Highland county have to be concentrated in a single hospital, and a smaller county has its isolation hospital merged in another hospital outside its boundaries against the unanimous opposition of its representatives.—I am, etc.,

Dundee, Scotland, July 16th.

W. HAMILTON, M.B.

Ligation of Thyroid Arteries in Toxic Goitre

SIR.—My friends Sir T. Dunhill and Professor Wilkie are, I gather, comparatively recent converts to preliminary arterial ligation in thyrotoxicosis, and in testifying to their changed opinions show that breadth of view which we expect from surgeons of their high skill and mature judgment. I was not only brought up in the faith, but for twenty years have proudly practiced the operation, yet I believe that the effect of your correspondents' letters would be to produce, in the minds of those less experienced than themselves, too optimistic a view of the value of the procedure.

Such benefit as accrues is independent of anything but the resulting diminution of blood supply, for there appears little to justify the assumption of ligation of associated lymphatics or nerves. If, then, the superior thyroid arteries carry a large percentage of the total arterial blood of the thyroid it is probable that, as in

CORRESPONDENCE

so often the case, the inferior arteries are the larger, the result is often disappointing; there is little or no clinical evidence of a fall in the activity of the toxic process or of favourable changes as estimated by basal metabolic and impedance angle tests. It must not be forgotten that, minor operation as it is, it has an appreciable mortality, and there is a by no means negligible minority in which the operation either aggravates the progress of the disease or at any rate entirely fails to check it.

The main value of ligation of the superior thyroid arteries is, I believe, as a test of the patient's susceptibility to surgical trauma, particularly in primary thyrotoxicosis associated with a large, intensely vascular goitre and great nervous excitability. If, as may happen, this trivial operation, conducted under local anaesthesia and occupying less than ten minutes, is followed by an intense post-operative reaction, then it clearly indicates that the major procedure would have been too hazardous.

At the Annual Meeting of the British Medical Association held in Edinburgh a few years ago, I heard the facile statement made that pre-operative iodine therapy had solved the problem of mortality in thyrotoxicosis. I did not believe this, nor do I believe that it can be solved entirely by the preliminary ligation of arteries.—I am, etc.,

London, W.1, July 21st.

Principles of Gynaecology

SIR,—I shall be grateful if you will allow me, on behalf of my collaborators—Mr. Datnow and Mr. A. C. H. Bell—and myself, to express our appreciation of the thoughtful and interesting review of the recent edition of *The Principles of Gynaecology*, which appeared in the *British Medical Journal* of July 14th (p. 65).

A textbook, your reviewer realizes, should be more than a sudden repetition of former views and methods, for science does not stand still: it should be not only a comprehensive and digested summary of moving events, but also an analysis and cinematograph of moving events. But what difficulties face those who undertake the task of incorporating intelligibly settled facts in a large tract of partly explored and ever-expanding territory! We feel, therefore, that, in saying our work will beneficially influence gynaecological thought, teaching, learning, and practice, your reviewer has said all we could wish him to say, for that has been our object from the first.

Your reviewer is curious to know why in this edition Part II (examination methods—previously Part III) is interposed between Part I (anatomy) and Part III (physiology—previously Part II). This is easily explained. Many functional conditions (Part III) require examination methods (Part II) for their elucidation. The anatomical phenomena (Part I) require chiefly dissectional methods.

To one knowing, as I do, the improvements which could be made, and which will be made in the next edition, your reviewer's choice of subjects for comment is a little surprising. Moreover, he seems sometimes to think that too much has been given, yet he asks for more! He writes:

"Here and there, however, broad principles are lost in detail. Thus the meaning and implications of the reduction of chromosomes during maturation are lost in describing the manner of their reduction. Neither among the possible causes of abortion nor under 'selective sterility' is there any reference to lethal gametic combinations, well recognized as cause of loss of zygotes in breeding experiments."

As a matter of fact, "the manner of their reduction" is not described at all, and brief mention only is made of reduction in respect of maturation of the ovum, and

of the relation of sex-chromosomes to sex differentiation in *Drosophila*. It is presumed that the subject of genetics, which is of such fundamental concern not only to gynaecology but to all branches of medicine, is taught earlier in the curriculum. On the other hand, in regard to the clinical implications to which reference is made, I would point out that special attention is drawn to malformation of the embryo as a cause of early abortion; so, as everyone knows that this may be ascribed to "lethal gametic combinations," it can hardly be said that there is no mention of them. Besides, to have discussed selective sterility in the human subject in relation to the same factors would probably have been erroneous; we should have to go back to Ciona for a possible biological (but not chromosomal) explanation, with which I need not trouble your readers. The one given is not unsound, and is of sociological importance.

With regard to the word "ponation," to which exception is taken, it is generally conceded that language given to us to express not only our thoughts but also the facts of the physical universe, in which removal of the whole uterus from one place to another is an event well known to gynaecologists. It has no other name; yet it is of diagnostic importance. Why should it not be so identified to avoid confusion, not to create it? Anyway, "ponation" has appeared in every edition of *The Principles of Gynaecology*, including the first (1910), and has never before been challenged. We all know, of course, the past participle of *pono*, but are reluctant abstractly to "depose" the uterus. The Americans have, however, gone one worse, for they have quite recently introduced the horrid term "cession"; they speak of "retrocession" in this connexion.

Last, concerning the beginner's sense of proportion, in all seriousness I would ask whether he is likely to boggle at three pages only (excluding illustrations) on the important subject of hermaphroditism, or at one and a half pages on lead therapy? We hope that your reviewer's remarks, generous though they are, will not discourage the student from taking advantage of the high opinion we have of his desire to learn.—I am, etc.,

W. BLAIR-BELL.

West Felton, July 17th.

Tuberculin

SIR,—May I endorse Dr. Camac Wilkinson's request for an impartial investigation into the tuberculosis problem. Almost every day there is evidence in the medical journals pointing to a grave lack of co-ordination between the organizations dealing with the disease, and there would seem to be apathy prevailing at the centre of control. I understand that there is a department of the Ministry of Health which has the right of inspection of such organizations. If this is so such a department will presumably collect a good deal of valuable and irrefutable evidence of the value of certain methods of attack. Surely it should pass on this information to all local centres.

Two topical instances will illustrate my point. (1) The list of experts and others who, as the result of *ad hoc* research, give tuberculin a high value in their armamentarium grows more and more formidable, and yet after forty years there are Government centres for tuberculosis which ignore its use. (2) We are indebted to Dr. Hope Gosse and Dr. Erwin for recording the valuable advice that sunbathing may be prejudicial to the tuberculous diathesis (*British Medical Journal*, July 7th). This fact would appear to be contrary to public opinion as educated by the daily press, etc. I think it is pertinent to ask whether the appropriate department at the Ministry of Health has seen this article, whether it believes the

CORRESPONDENCE

JULY 28, 1934]

conclusions drawn, and, if so, does it intend to pass on the advice to all tuberculosis centres under its control so that public opinion may be enlightened?

Apart from Royal Commissions, eulogistic conferences of voluntary associations, and personal opinions, it is easy to appreciate that we must have more co-ordination of official work if further progress is to be made in the conquering of the disease.—I am, etc.,

ALISTAIR R. FRENCH.

Greenford, Middlesex, July 16th.

SIR,—As Dr. Bardswell is, and has been for many years, one of the best-known tuberculosis experts, it would be absurd of me to offer an opinion contrary to his. I was his senior assistant at King Edward VII Sanatorium in 1909-10 when the work on tuberculin was being done, and I remember how disappointed I was when we stopped giving it. I had got most enthusiastic about it, and thought it a mistake to give it up. When at Benenden Sanatorium I used* it extensively, and as tuberculin officer for Essex I carried about four or five different tuberculins to the dispensaries and sanatoria under my care. The doctors were surprised that, as Dr. Bardswell had condemned it, I should go contrary to his teaching. Now I—like, I suppose, 90 per cent. of my colleagues—never use it. Why? Simply because I now believe with Dr. Bardswell that it has proved of no use. Imagination and tuberculin are good bedfellows. For Dr. Camac Wilkinson take no trouble to work at the size we other specialists take no mind, quite absurd. It is, if my surmise is correct, putting him and his few followers on an unjustifiable pedestal, and letting his genuine enthusiasm run an academic riot. Before artificial pneumothorax became popular we all, only too willingly, would have tried and continued to use anything to help our patients, and there must be a very large body of able and conscientious tuberculosis men who worked as hard as Dr. Camac Wilkinson did and yet never use tuberculin now. Its diagnostic value is practically nil, and therapeutically it is, in my opinion, as valuable as Dr. Bardswell dramatically described it the other day.—I am, etc.,

J. D. MACFIE.

Lexden, Colchester, July 18th.

SIR,—When I was in the West of England last January a friend of mine was lamenting the fact that all his pulmonary tuberculosis cases died, and made this remark: "I feel that something is being withheld from the public which they ought to have." He was perfectly right. Dr. Opie of America said tuberculin dispensaries should be opened in this country. Dr. Bredeck, in the *American Review of Tuberculosis*, April, 1933, writes:

"The Schilling blood count, together with the subcutaneous tuberculin test, constitute, in my experience, our most delicate and most accurate methods in the diagnosis of early manifest and induced focal activity."

To this should be added a medical history, taken with laborious care and by doctors with several years' experience in general practice. The solution of the triad—diagnosis of pulmonary tuberculosis lies in the triad—tuberculin, blood picture, and history of the patient. No other method will detect the first results of allergic tissue activity, caused by the action of the bacillus.

In Wingfield's *Textbook on Pulmonary Tuberculosis* (p. 342) is the following statement:

"The patient must be under close and skilled clinical supervision during a course of tuberculin treatment. It must not, for instance, be undertaken by the ordinary physician unless he has made a special study of the disease and treatment. A complete temperature and pulse record must be kept, with weekly weighings. There must be constant supervision of symptoms, none of which must be ignored."

The Local Medical Committee of the London Insurance Committee has decided that the administration of tuberculin "requires no special skill or experience." The Minister of Health has agreed with this decision.—I am, etc.,

H. S. BURNELL-JONES.

Hayes, Kent, July 13th.

Thrombosis of Internal Saphenous Vein

SIR,—I attended a strong, healthy man whose history was that on the previous day he had been helping to unload a lorry, a crate had slipped, and he had felt some pain over the inner side of his left knee-joint. On examination it was seen that he was suffering from traumatic phlebitis with thrombosis of the internal saphenous vein as it was passing over the joint. The clot was about three-quarters of an inch long. He was kept in bed exactly three months; the clot had diminished down to the size of about a split-pea, and felt hard. I thought that this must be fibrous tissue and that it would be safe to allow him to get up, so his wife got out all his clothes ready for the morrow, which was his birthday. At midnight she heard a gurgle, etc., in his throat, and on examination he was found to be dead. He was such a strong, healthy-looking man that this tragedy gave me cause for reflection, and I formed the opinion that in cases where it is possible to ligature the vein proximal to the clot this procedure appeared desirable. When it is impossible to reach the healthy vein above, then it should be cut down upon at the site of the thrombosis; its contents being thus freed from tension the production of embolism would be less likely. The cutting down on a clot becomes inevitable should there be the slightest suspicion that secondary infection has occurred.

In the following patients proximal ligation without incision over the thrombosed area was performed, and gave me an additional sense of security throughout their favourable convalescence.

The first case was that of a lady over 65 years old. The same vein became suddenly thrombosed from no apparent cause. After consultation, Mr. R. Kennon of Liverpool agreed to cut down on the internal saphenous vein in the thigh, ligature it in two places about two inches apart, and remove the portion of vein in between: uninterrupted recovery; stitches removed on tenth day; patient was up the fourteenth day, although the thrombus seemed just about the same. She gradually got about, although it was months before the thrombus had all disappeared; in the meantime she went about her daily work as usual.

In another case a lady, aged 46 years, had been shopping in town during a cold winter's day, and felt pain on the inner side of the knee-joint and just below. When she got home it was found that part of the vein was thrombosed. Mr. Kennon advised that a pad should be placed over the proximal part of the vein and strapped firmly round the thigh. A few days later, whilst she was being visited, she suddenly collapsed; all blood left her face, which turned ashen grey; breathing was irregular and jerky, and she lost consciousness. Deep and vigorous cardiac massage, accompanied with upward pressure under the left costal margin, was immediately begun, fortunately with good results. Mr. Kennon repeated the same operation as before: the patient was up in a fortnight, and gradually got about her usual duties in spite of the thrombus, which was eventually absorbed.

Other cases operated upon in the same way have invariably done well—up in a fortnight and walking about in three weeks. These cases would not have been reported, but in a recent book on surgery it is stated that very prolonged rest is required for these patients. The author quoted a case that he had had at rest for a considerable time, but for domestic reasons it was advisable for the patient to be nursed downstairs. The patient

was very carefully carried down, and all seemed well, but he suddenly dropped back dead.

I hope that these few remarks may be of service to others.—I am, etc.,

Hastings, July 17th.

A. STANLEY PARKINSON.

A Case of Angular Pregnancy?

SIR,—In view of Professor Munro Kerr's article upon "Angular Pregnancy—A Clinical Entity," and his request for details of any such cases, which appeared in the *British Medical Journal* of June 23rd, I venture to publish the following brief account of a case which I encountered in hospital practice. I feel that publication of this case may be excused on the grounds of its own interest, but, what is more important, it may elicit further records.

A young married woman, aged 24, was admitted to the Royal Berkshire Hospital on November 28th, 1932, as an "acute appendix." She had been in sound health till the morning of the day of admission, when she developed pain in the abdomen, at first vague but later becoming increasingly severe and situated in the right side. There was no vomiting, and the bowels were open normally. There were no symptoms suggestive of urinary disorder.

On admission the patient did not look gravely ill, but was obviously having pain. Temperature 98.4° F.; pulse 96. Tongue slightly coated but moist. The abdomen was normal in contour, with fair respiratory movement. She was very tender in the right iliac fossa, with definite resistance to the palpating hand, but not true rigidity. The chest was clear and the urine examination revealed no abnormality.

Only upon close questioning did she admit that she had missed two menstrual periods; the second of these had been due a few days prior to admission. In the interval between the visit of her own medical practitioner and her removal to hospital she had had a slight loss from the vagina, which she took to be the onset of her period. Previously the menses had always been regular and unaccompanied by pain. Examination per vaginam revealed only a slight loss. The cervix was closed.

In view of the tenderness and defensive tightening it was decided to operate upon a diagnosis of acute appendicitis. The abdomen was opened through a median sub-umbilical incision. There was no blood or free fluid in the peritoneal cavity. The appendix was innocent and the intestines normal, with no enlargement of abdominal glands. The stomach and gall-bladder were normal. The uterus was enlarged to about the size of a two-months' pregnancy, but was quite asymmetrical. There was a definite, tubular, elongated swelling at the right upper pole of the uterus just immediately proximal to its junction with the right Fallopian tube. Tubes and ovaries were normal. The abdomen was closed without any further operative procedure.

The patient aborted completely two days later, but the specimen was not kept. Recovery was thereafter uneventful, and she was discharged from hospital well.

WILLIAM H. GOSSIP.

Cyanide Poisoning: Rasputin's Death

SIR,—In connexion with the letter on this subject from Dr. Frederick Dillon in the *Journal* of July 14th (p. 88), I think it is unnecessary to suppose that Rasputin's apparently miraculous survival after partaking of many lethal doses of cyanide was due to the powder administered to him not, in fact, being cyanide at all. Prince Youssouppoff's account of the drama includes a description of Rasputin's symptoms after taking the poisoned cakes and wine—for example, bitter taste, attempts to swallow an apparent obstruction in the throat, drowsiness, headache, extreme thirst, and finally a burning sensation in the stomach and a dull appearance of the eyes (occurring about an hour and a half after the beginning of the meal). This account (by a layman) agrees quite well with the

symptoms of cyanide poisoning as detailed in books on pharmacology.

It is a well-established fact that cyanides will combine with the keto and aldehyde groups in the simpler carbohydrates to form cyanhydrins (Kiliani's reaction). De Saint Rat (*Presse Méd.*, 1926, xxxiv, 34, 1268) showed that when potassium cyanide was added to port to the extent of 2 per cent., three-quarters of the cyanide had disappeared as such from the wine after three hours, and no trace could be detected after nineteen hours; the wine contained 8.5 per cent. of reducing sugar. The cakes into which powdered cyanide was inserted by Rasputin's murderers contained "chocolate cream"—that is, included sugar and milk—and there is little doubt that some of the cyanide would likewise be chemically bound in them.

Various investigations (Vielle: *Bull. de l'Acad. de Méd.*, 1926, xcv, 644; Forst: *Arch. Exper. Pathol. u. Pharm.*, 1928, cxxviii, 1) have shown that cyanide intoxication can be largely avoided by the previous administration of glucose to animals; and a case has been recorded of an individual who, by mistake, drank some sweetened tea containing two to three lethal doses of cyanide without suffering more than slight indisposition an hour later. Some experiments which I carried out a few years ago in collaboration with Dr. A. W. Forst indicated that it is possible to protect animals from many lethal doses of cyanide by previous administration of certain carbohydrates, or by previous admixture of carbohydrate with the cyanide, and that various carbohydrates differ markedly from one another in their capacity to protect. These differences do not depend entirely on the rate and extent to which the carbohydrates combine with cyanide *in vitro*, and can only be fully accounted for by some biological peculiarity as well.

I would not contend that Rasputin's survival after taking the poisoned food and wine was due solely to the protective action of the sugar contained in them; although, as the preparation was carried out some hours beforehand and conditions were thus suitable for the detoxication of the cyanide, it must surely have been an important factor. A pre-existing gastritis, as suggested in your quotation from Leschke, would no doubt assist in the protection against cyanide poisoning, and there may have been other factors which have not yet been investigated.—I am, etc.,

University of Bristol, July 16th. R. J. BROCKLEHURST.

SIR,—We are told that on December 29th, 1916, Rasputin was shot and his body flung into the Neva. A few hours before the fatal shot Rasputin is said to have eaten three chocolate cakes heavily charged with potassium cyanide. This deadly stuff, which was swilled down with three glasses of poisoned wine, appears to have had no effect on Rasputin. Two hours later he was in vigorous health, and, like the man in the gum-boots, who bounced for a fortnight, he had to be shot to end his activities.

Before we assume that the debauched and unsavoury body of Rasputin was protected against large quantities of cyanide of potassium by natural immunity, alcoholic gastritis, or supernatural agency, we must be sure that he consumed and retained the poison. Of this there is no certain evidence. The uncorroborated statement in Prince Youssouppoff's book quoted by Dr. Dillon would not be accepted by a conscientious detective. The most reasonable explanation of Rasputin's escape from cyanide poisoning is the one suggested by Dr. Dillon—that the powder in the cakes was not cyanide of potassium at all. If Dr. Lazover tried to poison Rasputin he bungled his job.—I am, etc.,

Birmingham, July 16th.

OBITUARY

THE BRITISH MEDICAL JOURNAL 185

"Use Less Water"

SIR.—The gravity of the water shortage in the United Kingdom encourages me to give a mere medico's impressions culled on leave during the initial stages of the drought. To one accustomed to very careful preservation of water in Palestine, particularly in Jerusalem, the wastage of water in and about London seemed criminal, and two aspects are prominent in my mind.

1. In most of the operation theatres I had the honour of visiting water was allowed to flow *ad lib.* for no cleansing reason, it seeming to be taken for granted that hospitals had a special liberty in this respect. I have seen in one theatre more water running away to the drain through an unstopped basin (the tap left running by a surgeon or nurse) during one morning's operations in Jerusalem. This could be obviated by notices over basins, such as "Use water more carefully" rather than "Use less water"; also, if a slow-action spring were put on some of the lever-controls of taps, the latter would automatically shut.

2. The general use of sprays in houses hardly exists. If it were only realized that less water is used in a spray, either overhead or hand, a flexible connexion to ordinary taps could be used, even on a geyser. On the other hand, most people do not appreciate a spray. The Arab considers we are probably a dirty race, as we need so many baths; but what puzzles him is why "Inglese" prefer a soaking in their own dirty water, rather than a gentle, fresh stream all the time and no dirty water to dry off! Sprays do this, but in Great Britain they are conspicuous by their absence—at least to one who toured in quite a normal manner both England and Scotland. I can assure you there is nothing quite so refreshing after a long journey as a spray, rather than a tub.—I am, etc.,

W. E. THOMPSON.

Jerusalem, July 8th.

Agranulocytic Angina

SIR.—I must apologize to Dr. Bulmer for having over looked the report of his case. I should also, perhaps, have mentioned that in the case I reported the patient had not previously taken amidopyrine or a barbiturate or any combination containing them.—I am, etc.,

A. DALY BRISCOE.

Woolbridge, Suffolk, July 22nd

The Services

DEATHS IN THE SERVICES

Lieut. Colonel Jeremiah Pennv. Madras Medical Service (ret.) died at sea, on the voyage home from India, on July 7th, aged 70. He was born on July 5th, 1864, the son of William Pennv. of Langport, Somerset, was educated at King's College Hospital, where he was Warneford scholar, and took the M.R.C.S., L.R.C.P. Lond. in 1887, and the D.P.H. Camb. in 1891. After filling the posts of house-surgeon, house-accoucheur, and resident house physician for women and children at King's College Hospital, and of house-surgeon at St. Peter's Hospital, he entered the I.M.S. as surgeon on July 28th, 1891, became lieutenant-colonel after twenty years' service, and retired on September 25th, 1921. He served in the Chin Hills campaign, on the North-East Frontier of India, in 1892-3, receiving the Frontier medal with a clasp. Most of his service was spent in civil employ in Burma, and after retiring he settled at Rangoon, near Rangoon. He leaves a widow.

Surgeon Lieutenant (R) John Wade Robinson, L.D.S. R.N., of H.M.S. *Deception*, was shot by Turkish snipers while battling with two other officers at Tiberias on the island of Samos. One of the other officers was wounded at the same time. The officers apparently mistook the officers in their boat for snipers. The Greek snipers.

Obituary

MARMADUKE STEPHEN MAYOU, F.R.C.S.
Senior Surgeon, Central London Ophthalmic Hospital

The death, on July 20th, of Marmaduke Stephen Mayou has prematurely removed from the world of ophthalmology one of its most forceful and prominent figures.

Born at Monmouth on May 4th, 1876, the son of George Mayou, M.D., he was educated at Hereford Cathedral School, and chose King's College and the London Hospitals for his medical studies, winning there the Warneford Scholarship and Jeff Medal in 1896, and qualifying M.R.C.S., L.R.C.P.

He held the Hunterian Professorship of the Royal College of Surgeons in 1905, thus entering brilliantly a distinguished scientific career. The list of Mr. Mayou's appointments, though long and varied enough to make formidable reading, by no means covers his vast activities. The breadth of his interests is shown by the number and diversity of the papers, devoted to pathology, comparative pathology, and clinical ophthalmology, he contributed to the *Royal London Ophthalmic Hospital Reports*, *Ophthalmoscope*, *Transactions of the Ophthalmological Society of the United Kingdom*, *Proceedings of the Royal Society of Medicine*, *British Journal of Ophthalmology*, *American Journal of Ophthalmology*, *British Medical Journal*, *Lancet*, *Practitioner*, and *Archives of Roentgenology*. Among his most notable publications are "The Changes Produced by Inflammation in the Conjunctiva" (Hunterian Lectures), *Diseases of the Eye* (which has run into four editions), and, in collaboration with Treacher Collins, *Pathology and Bacteriology of the Eye*.

His association with Mr. Treacher Collins was not limited to authorship, since, in 1927, he followed him in his post of visiting ophthalmic surgeon to the White Oak Hospital, Swanley, and shared his keen interest in the study of eye diseases in children; he was tireless in furthering the important work done at this hospital. Mr. Mayou's work in this direction was of the widest possible nature, and his experience was vast. He was appointed consulting surgeon to St. Margaret's Hospital, Kentish Town, at its opening in 1918, and to the Foundling Hospital, and he fully recognized the importance of the former as a teaching centre for medical students and midwives. At the time of his death he was also ophthalmic surgeon to the Bolingbroke Hospital, the Ear, Nose and Throat Hospital, Golden Square, the Infants Hospital, Vincent Square, and the Charterhouse Rheumatic Clinic. Among former appointments were those of ophthalmic surgeon to the Children's Hospital, Paddington Green, to the Hospital for Epilepsy and Paralysis, Maudsley, and to the Seamen's Hospital, Greenwich.

The hospital with which his main energies have been associated, and to which his name will be best directed, is the Central London Ophthalmic Hospital, King's Cross, of which he was senior surgeon. He was appointed to the hospital as pathologist and radiographer

in 1906, became assistant surgeon in 1907, full surgeon in 1911, and succeeded Mr. Ernest Clarke as senior surgeon in 1913. Until the day of his death Mayou was unremitting in his efforts for the improvement and perfection of this hospital. No detail was too small for his attention, and his enthusiasm and ambition for its welfare and efficiency were boundless. It was mainly owing to his instrumentality that private wards for patients of limited means were added to the hospital, under the name of the Princess Marie Louise Wing, and he personally supervised each step in the fitting and furnishing of these rooms. On committees, executive and consultative, Mayou was always definite in his views, and his presence was recognized as of the greatest value. After serving first on the council and then as vice-president he was chosen as president of the Ophthalmological Society of the United Kingdom, and he was holding this important office at the date of his death. He was an original member of the Section of Ophthalmology of the Royal Society of Medicine, treasurer of the Council of British Ophthalmologists, and a member of the editorial and executive committee of the *British Journal of Ophthalmology*. He was a representative of the Council of British Ophthalmologists on the Ophthalmic Committee of the B.M.A. Other activities in the British Medical Association included that of the Association's representative on the National Ophthalmic Treatment Board in 1930. An active Freemason, he was Master of the Captain Coram Lodge, and ophthalmic surgeon to the Royal Masonic Hospital, first at Fulham and then at Ravenscourt, and to the Masonic Schools at Weybridge and Clapham Junction.

It is impossible here to do more than touch lightly on Mayou's manifold activities, but even from what has already been said some small idea can be gleaned of his limitless energy and unflinching interest in the branch of medicine which he had made his life's work. His patients—private and hospital—reaped the benefit of his extensive experience, and their absolute confidence in his opinion and treatment was shared by his colleagues, while his well-recognized skill in operating earned him the respect of those privileged to watch him. His interest in the mechanical side of ophthalmology is demonstrated by the numerous instruments he invented, the most notable of which are the Mayou operating lamp and the Mayou slit-lamp.

Thus far the ophthalmologist, who concealed the man himself. Broad in his views and far-sighted, he was primarily a sportsman. In spite of the incessant calls upon his time Mayou was an enthusiastic fisherman, spending some time of each year in Scotland, Norway, or Ireland in this pursuit, and enjoying nothing better than talking "fish" with others of the same cult. Indeed, the beginning of his last series of illnesses might be attributed to his over-enthusiasm in fishing in the chill waters of an Aberdeenshire river. A keen golfer, he fostered the yearly golf match between the Central, Moorfields, and Westminster Eye Hospitals with a jealous and paternal care. He was an ardent horticulturist, full of wise and helpful advice. His practical-mindedness was as evident in his private life as in his work, and his opinion on antiques was as interesting as it was instructive. A kindly and delightful host, always ready with counsel for those who sought it, either on private or professional grounds, his knowledge and experience, and the rapidity and clarity with which his mind worked, did not permit him to suffer fools gladly, and when he had made up his mind as to the right and proper course to pursue nothing would turn him aside from his purpose.

He is survived by a widow and three daughters.

[The photograph reproduced is by Elliott and Fry.]

CHARLES J. HEATH, F.R.C.S.

Mr. Charles Joseph Heath died at his house in York Terrace, Regent's Park, N.W., on July 13th. He was well known as an aural surgeon, as a sportsman, and as an inventor—showing a versatility which is not unusual in members of the medical profession, but which in his own case covered an unusually wide sphere. As aural surgeon he correlated the best points of many operations on the ear, tested them by experience, and produced a method which his friends always spoke of as "Heath's operation." He was somewhat vain of the method, and spoke of it in season and out, sometimes to the weariness of his auditors. The operation is a good one, is likely to be lasting, and was worthy of his praise. He designed, or modified, too, a large number of instruments for use in the surgery of the ear. As a sportsman Heath was a first-rate shot, and was equally good as a salmon fisher. He shot wildfowl on the Shannon and in Essex, and fished in Galway. As an inventor he designed and improved an anti-gas helmet of which large numbers were supplied to the British Army during the Great War, and introduced a chamberless wildfowling gun. He also defined the principles essential in the design of Army boots for the Army Hygienic Advisory Committee.

Born at Totnes, South Devon, on Christmas Day, 1856, he was the third son of John Heath, land agent, and Rachel Pulling, his wife. His elder brother, William Lenton Heath, F.R.C.S., who died in 1912, was well known and very popular as a general practitioner in South Kensington. Charles Heath was educated at the King Edward VI Grammar School at Totnes and at St. Bartholomew's Hospital. At the latter he early showed his delicate manipulative skill by gaining, in successive years, and at a time when there was very keen competition, the junior and senior prize for the best dissection. He was subsequently appointed Prosecutor at the Royal College of Surgeons, where it was his duty to make the dissections upon which candidates for the Membership and Fellowship of the College were afterwards examined. He was admitted M.R.C.S. in 1884, served a term of office as house-surgeon at the Preston Royal Infirmary, and was elected F.R.C.S. in 1886. Two years later he joined the British Medical Association, for which he afterwards did good service as secretary of the Section of Laryngology. Having determined to practise a specialty, he became assistant surgeon to the Central London Throat, Nose and Ear Hospital, and afterwards to the Throat Hospital in Golden Square, where at the time of his death he was a vice-president. Aural surgery attracted him more than the treatment of diseases of the throat, and he was for some years the consulting aural surgeon to the Downs Hospital for Children under the Metropolitan Asylums Board. He was a Fellow of the Hunterian Society, and was a frequent speaker at the British Oto-laryngological Society and at the Oto-laryngological Section of the Royal Society of Medicine.

He wrote little, his chief contributions to the literature being: *Diagnosis and Treatment in Cases of Otitis Media*; *The Cure of Chronic Suppuration of the Ear Without Removal of the Drum or Ossicles or Loss of Hearing*; *The Nature and Causes of Catarrhal Throat or Hereditary Deafness with a New Method of Treatment*; *The Prevention of Deafness and Mortality which Results from Aural Suppuration*.

He married Agnes Frideswide, daughter of Colonel J. J. Wilson, who died in 1930, and is survived by two daughters. Heath was a true sportsman and a loyal friend. He suffered of late years from increasing deafness, which led him last year to resign his position as a member of the House Committee of the Governors of

St. Bartholomew's Hospital, a position he greatly valued. The funeral service was held at St. James's Church, Piccadilly, and he was buried at the Greenwich Cemetery, Shooter's Hill.

IV. STEEL of Bournemouth died on July 14th 1934, aged 67. He was born at Dundee and educated at the University, he graduated at Bolton.

Dr. JAMES W. STEEL of Bournemouth died on July 14th, in his early forties. Born at Dundee and educated at the Morgan Academy and Edinburgh University, he graduated M.B., Ch.B. in 1913. After acting as house-surgeon at Bolton Infirmary he was assistant in private practice in Preston before joining the R.A.M.C. in 1916. He held the rank of captain, and suffered severely from malaria and dysentery in Salonika. For his war services in Batum and South Russia he was awarded the Order of St. Stanislaus. Mr. R. Saunders Melville, F.R.C.S.Ed., writes: "I was touched to read recently in a book of war reminiscences by a much travelled member of the medical profession numerous references to "Jimmy" Steel. He mentions his charming smile, his universal popularity, his skill as a pianist, which gave pleasure to so many during those arduous days, and he refers to him as the most conscientious man he had ever met. That is no exaggeration. The charm of James Steel's personality lay in his simplicity, and his modesty. Therein lay his goodness of heart, and his modesty. He loved life and strength. His was a sunny nature, and he loved life and happiness. He settled in Bournemouth after the war, rapidly built up a large practice. He was by nature the ideal family doctor, and his abilities were far in excess of his very modest estimate of them. His devotion to his profession was absolute, and he carried out his duties until within a few days of his death. When told that he was suffering from leukaemia and advised to go up to London for x-ray treatment, it was typical of him to say that he really could not go at that time as he had a "confinement coming off." He knew that there was no prospect of cure, and his one anxiety seemed to be that it should make "no difference." He refused to submit to invalidism. He carried on his practice with the help of an assistant, went on holiday with all his old enthusiasm, and it says much for his strength of character that he was able to forget and almost able to make his friends forget that he was fatally ill. He met the remonstrances of his doctor brothers and professional friends with obvious indignation, and argued with a whimsical wit that invariably brought the laughter that he loved so much, but he submitted to spare them anxiety—not for his own sake. Last winter he confounded the critics by dancing an eightsome reel with all the grace and skill inherited from his Highland forebears. Dr. Steel was unmarried, but he was fortunate in being a member of a devoted family. His mother, to whom he was deeply attached, predeceased him about two years ago, spared the knowledge of her son's illness. Children loved him; he was fond of saying that he was honorary uncle to numerous small patients. His last days were brightened by the company of a small nephew, who frequently went with him on his rounds and whose quaint sayings were of far more interest to him than his own symptoms. And now he is gone, dying as he had lived, a very gallant gentleman. We his friends, in extending our sympathy to his family, share very humbly in their pride in him.

The death of Dr IRENE CLARKE (née Higgie) has removed a zealous worker from the British Medical Association, as well as an energetic and devoted servant of the community. Irene Higgie graduated M.B., Ch.B.Glas. in 1923, and joined the Association immediately. She obtained the D.P.H. in 1928. In the next year she married Dr T. W. Clarke of West Acton, and thereafter was prominent in the social life of Acton and Ealing, and a strong supporter of various charitable causes. One of her chief interests was the Acton Hospital, to which she rendered exceptionally valuable assistance. She became honorary secretary of the West Middlesex Division of the British Medical Association in 1930, and was a Representative at the annual meeting in 1931 at Eastbourne. Until her last illness she had been very active in work for the Division, interesting herself in all sides of medical progress. She was a life member of the British Association

for the Advancement of Science, and a Fellow of the Royal Institute of Public Health. To a real devotion to scientific knowledge she added a great ability for organization and genius for hospitality. What had promised to be a brilliant and happy career was cut short by a lingering illness, and it is hoped to commemorate in some useful way a life which, though short, had been full of inspiration and encouragement for others.

Fridjohn, A. E. Fannin, Eva E. Moore, H. A. Wells, P. Cutron.

DIPLOMA IN PUBLIC HEALTH.—*Part II*: A. J. O'Connor, Anna M. E. McCabe, R. A. J. Holmes-Jevers, I. G. M'Intyre

* Passed on high marks.

The following prizes have been awarded: *FitzPatrick Scholarship*: F. M. Hanna. *Medical Scholarships*: Physics, Chemistry, Botany, and Zoology, G. E. Nevill; Anatomy and Physiology, J. H. A. Jewell. *Stewart Medical Scholarships*: Physics, Chemistry, Botany, and Zoology, S. Sevvit; Anatomy and Physiology, G. N. MacFarlane. *John Mallet Purser Medal*: J. E. Gillespie. *D. J. Cunningham Memorial Medal and Prize*, G. N. MacFarlane. *Begley Studentship*, D. K. Stewart. *O'Sullivan Memorial Scholarship*, J. N. P. Moore. *Adrian Stokes Memorial Fellowship*: G. C. Dockeray, E. S. Duthie. *De Renzy Centenary Prize*: Anna M. E. McCabe. A. J. O'Connor. *Agnilla Smith Prize*: D. T. Bardon, C. Mushatt. *Walter G. Smith Prize*: G. B. Jackson.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week voted all outstanding estimates. The *Cattle Industry (Emergency Provisions) Bill* was passed.

The *Domiciliary Nursing Services Bill* was read a second time without debate in the Commons on July 20th, and was sent to a Standing Committee.

In the House of Lords, on July 23rd, the Commons Amendments to the *Shops Bill* were accepted, and consequential amendments were made.

Parliament will adjourn for the long recess on July 31st, and probably reassemble on October 29th to complete the work of the present session, including the Betting and Lotteries Bill.

During the latter part of the recess Sir HILTON YOUNG will visit large towns in England and Wales to explain the Government's plans for preventing overcrowding, and to inspect the progress made in slum clearance. This action is independent of the discussions proceeding on the provisions of the forthcoming Overcrowding Bill with the London County Council and the accredited associations of local authorities.

The House of Commons, on June 20th, ordered a return of licences granted under the Act 39 and 40 Vic., cap. 77, showing the number of experiments on living animals performed under the Act during 1933, and the registered places at which such experiments may be performed.

Houses for Wage-earners

In the House of Lords, on July 18th, Lord BALFOUR OF BURLEIGH moved a resolution declaring that, in addition to the slum clearance proposals of the Government, 1,000,000 houses should be provided to let at weekly rentals inclusive of rates of 10s. and under, and that the Government should consider setting up a Housing Commission to secure the erection of such houses by local authorities and public utility societies on a national plan. Lord AMULREE, supporting the resolution, said it was estimated that the next census would show an increase of 668,000 in the number of families in England and Wales compared with 1931. He argued that a similar number of houses would be required for them. The plea for a housing commission was supported by the Archbishop of Canterbury and other Peers. The Earl of CRAWFORD drew attention to the infestation of vermin in new housing areas in London. One group of students of the subject, he said, had estimated that 2,000,000 of the inhabitants of London were within the area of infestation, and the area was rapidly extending. Medical men who worked in these areas agreed that the bug produced a troubled form of sleep, resulting in debility and weakness, which was a source of general ill-health. It had been proved that the bug could get through the party wall of an average new residential house and take advantage of every nook and cranny and oversight on the part of the builder. He urged the Government not to rush the housing programme until it had an assurance that the new houses would not be infested in a year or two, and also not to begin to rebuild immediately upon cleared slum areas. Lord JESSEL said it was not the case that enormous numbers of workers in this country earned less than 50s. and so required very cheap houses. Moreover, the increased number of families included single persons, who, for census purposes, were reckoned as families.

Viscount HALIFAX said this was the fifth debate on housing which the House of Lords had held within seven months. The danger of the bed-bug was present to the mind of the Ministry of Health, and the proposals made on the subject by Lord Crawford would be brought to the attention of the Minister. The motion moved by Lord Balfour proposed a Housing Commission largely or partly to supersede the Ministry of Health. Such a body would be a barrier between the local authorities, who were immediately responsible for housing, and the driving force of the Minister and the Ministry. Direct contact with the Ministry gave the best

nothing to justify this suspicion. On the whole, the Department of Education was satisfied with the menu of school meals, which was mainly supervised by medical officers of the local authorities. The discussion then closed.

Noise from Motor Car Exhausts

The Road Traffic Bill was again taken in committee of the whole House by the House of Lords on July 19th. Lord ELTON, in the absence of Lord HORDER, moved to insert, after Clause 33, words making it unlawful to sell, to offer for sale, or to supply a motor vehicle for use on the road if such use would be unlawful under Section 3 (1) of the principal Act. The object of the amendment was to reduce the dangerous public nuisance of the excessively noisy exhaust of the motor car or motor cycle. To use on the roads a motor vehicle with an inefficient silencer was already illegal, but it was not illegal to supply such a vehicle. Under the Road Traffic Act, 1930, regulations provided that motor vehicles should be equipped with efficient silencers, but these regulations were openly and deliberately flouted because users of vehicles with illegal silencers satisfied the court that they had bought in good faith the standard production of a well-known firm exhibited for sale without restriction. The MARQUESS OF SALISBURY said that when a distinguished physician had told the public and the House of Lords that this evil was really antagonistic to public health the time had arrived to do something. The EARL OF PLYMOUTH, for the Government, appealed to the House not to press the amendment. The matter had been referred to the scientific committee, which the Minister had asked to report at the earliest possible moment. Despite Lord Plymouth's plea the House agreed to the amendment. Lord ELTON then moved a consequential clause making it unlawful to alter any motor vehicle or trailer in such a manner that the use thereof on a road would, by reason of such an alteration, be unlawful under the provisions against noise. The House also agreed to this amendment. Further amendments, chiefly of a drafting character, were made in subsequent clauses and schedules.

Veterinary Officers under the Milk Bill

The House of Lords, on July 19th, went into committee on the Milk Bill. On Clause 9 (payments for securing pure milk supply) Lord STRACHAN moved that at least half the sum provided under the clause should be allocated for making grants to county councils for the provision and maintenance of a whole-time veterinary service. He said the amendment was put down on behalf of the County Councils Association. The object of the clause should not be merely that a certain number of persons should produce pure milk to get an extra penny. All the herds of the country should be in such a condition that milk was always pure and free from infectious disease.

Earl DE LA WARR replied that a misunderstanding had arisen because there were two distinct schemes for cleaning up herds. The one which was affected by the finance of this Bill was the Ministry's scheme for building up tubercle-free herds. To enter it a herd-owner would have to satisfy the Government that he had had two successive tests at intervals of six months which showed his herd to be completely free. The Ministry would thereafter, within sixty days, carry out its own test through its own central service. The Government estimated the cost of the premiums on milk produced from herds so tested at approximately £450,000 over a period of four years. There was a further scheme which did not come under the Bill at all. This was the accredited herds scheme, to be prepared and administered entirely by the Milk Marketing Board. This would be approximately on the line that every herd should be open to clinical inspection twice a year, and that the milk produced should come up to Grade "A" standard. No expense would fall on a county council under the Ministry's scheme. Under the Board's scheme the counties might find it necessary to provide more veterinary officers, but all new expenditure for that purpose would have to be carried by the county until the block grant was next revised in 1937 or 1938. Under the Bill not a single county veterinary officer would have to be appointed.

The proposed amendment was defeated by 41 to 23. Subsequent clauses of the Bill were then carried with minor amendments.

In the House of Lords, on July 24th, the Milk Bill passed the report stage.

Poor Relief in Scotland

In the House of Lords, on July 23rd, the Poor Law (Scotland) Bill was considered in committee. On Clause 7 (which provides that an able-bodied person may be required by the local authority to perform work on a certificate of the medical officer that he is physically fit to perform the work) Viscount GAGE, for the Government, moved an amendment, allowing that the certificate might, in the case of a person who had a regular medical attendant, be given only after consultation with that medical attendant, whenever there was a reasonable opportunity of consulting with him. The purpose of the amendment, he said, was to ensure that the medical officer of the local authority should become aware of the applicant's medical history before granting a certificate. The amendment was accepted.

On Clause 11, which governs the granting of outdoor relief to members of friendly societies, Viscount GAGE moved an amendment to secure that the normal maternity benefit of 40s. should be disregarded. He said that this provision was agreed to in principle in the House of Commons on the clear understanding that the words he was now proposing should be added. In the case of an insured married woman authorities would be required to disregard the normal benefit, and it would be within their discretion in an individual case to ignore any increased or second maternity benefit. The amendment was agreed to, and the Bill passed through committee.

On July 24th the Bill passed the report stage.

Tarred Roads and Lung Cancer

On July 23rd Mr. SHAKESPEARE, replying to Mr. CLARRY, said that the Minister of Health was advised that a relation between the inhalation of dust from tarred roads and cancer of the lung had not been established; it was, therefore not possible to say whether any deaths from this disease could be attributed to this cause. Sir A. SAMUEL asked if the Minister had any record or information to show why there was a great increase in the number of recorded cases of cancer of the lung. Mr. SHAKESPEARE: I would not put it as high as that. The percentage of cancer of the lung is very small. Sir F. FREMANTLE asked if the Minister was aware that the number of deaths from cancer of the respiratory organs was only 90 per 1,000,000 compared with 1,500 altogether from cancer generally. He also asked if the so-called statement of correlation was only a chance suggestion made by a layman without any qualifications, and that medical opinion considered it unwarranted. This question was not answered.

Artificial Teeth: Increased Import Duty

In the House of Commons on July 24th Dr. BURGIN moved that the House approve an Order imposing additional duties on imported artificial teeth. Mr. RHYDS DAVIES said he believed that the duty would amount to about 1½d. per tooth, and he would like to know whether a request for the duty had come from the dentists or from the manufacturers of teeth in this country. Dr. BURGIN said that there were about 30 million artificial teeth used each year in the United Kingdom. Ten millions of these were manufactured at home and about 20 millions were imported. The British industry was in a position to meet the whole of the requirements of modern dentistry in this country, and to supply all United Kingdom users with teeth of home manufacture. The imported teeth came from the United States of America, Palestine, Germany, France, and recently Japan. The highest duty payable on a single tooth was just under 1½d. The lowest price payable for an operation which involved the supply of a single tooth under national health insurance was 5s., and a duty which could not in any circumstances amount to more than 1½d. a tooth would not increase the cost of

MEDICAL NEWS

JULY 28, 1934]

a denture to the consumer. Mr. DAVIES asked whether an agreement had been come to with the dentists to that effect. Dr. BURGIN said that the committee which had examined this matter was of opinion that the increase in duty would not affect the price paid by the consumer. The motion was carried.

Fee to Hospitals for Road Casualties

In the House of Lords on July 24th the Road Traffic Bill passed the report stage. On Clause 13, which deals with payment and insurance in respect of emergency treatment, the EARL OF PLYMOUTH moved amendments providing that where emergency treatment is first effected in a hospital, the payments of 12s. 6d. in respect of each person, and of 6d. for every mile or part of a mile in excess of a distance of two miles, should, as far as possible, be made to the hospital. He said that it was quite obvious that the hospital could not travel to the scene of an accident, and therefore this mileage provision would not apply. The amendments were agreed to.

Economy Cuts.—Mr. SHAKESPEARE, replying on July 24th to Mr. D. G. Somerville, who asked what arrangements had been made to restore in part to doctors and chemists the losses suffered by them as a result of the economy measures of 1931, said a circular had been issued by the Ministry of Health to Insurance Committees on June 20th. This set out the arrangements for giving effect to the decision of the Government to restore, from July 1st, one-half of the deduction made from the remuneration of insurance practitioners and chemists, as a measure of economy, from October 1st, 1931.

Increased Importation of Surgical Appliances.—Dr. BURGIN told Sir C. Fox, on July 19th, that he was aware that imports of dental, surgical, medical, and veterinary instruments and appliances (except optical) had increased from £163,813 in the first half of 1932 to £215,250 in the first half of 1933, and to £247,022 in the first half of 1934. Any increase in the duty on these goods must be dealt with by the ordinary procedure under the Import Duties Act.

Notes in Brief

Sir Hilton Young stated that the interim report from the Advisory Committee on the Disposal of London Refuse will be received before the end of July.

Medical News

The next lecture-demonstration arranged by the Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.1) will be given at 11, Chandos Street, Cavendish Square, on July 31st, at 2.30 p.m., on sciatic pain. There will be no lecture on August 7th, but the series will continue on August 14th, with a lecture-demonstration on hysteria. On August 11th, at 3 p.m., at the National Temperance Hospital, Hampstead Road, Dr. H. V. Morlock will give a demonstration on chest cases. Mr. Alan Gairdner will give a short course on the treatment of recent and old fractures at the St. George-in-the-East Hospital, at 2.30 p.m. each afternoon from August 13th to 17th. Throughout August, daily instruction in various branches of medicine and surgery is provided by the panel of teachers.

The twentieth International Congress on Alcoholism will be held at the Imperial Institute, South Kensington, from July 30th to August 3rd, under the presidency of Lord Astor. The following papers, among others, will be read: "Licensing Legislation in Europe," by Dr. R. Hercood of Lausanne; "Legislation on Inebriety," by Dr. E. Gabriel of Vienna; "Alcohol Consumption and Specific Male Mortality," by Dr. R. Bandel of Nuremberg; "Alcohol in the Treatment of Disease," by Dr. J. D. Rolleston of London; "Alcohol and Eugenics," by Professor H. Gachot of Strasbourg; and "The Causes and Treatment of Inebriety," by Dr. A. E. Carver of Caldecott Hall. National surveys covering the present

position of the alcohol problems from educational, economic, medical legislation, and other points of view will be contributed by various speakers, and special addresses will be delivered by Sir William Willeox on the toxicological aspects of alcohol and drug addiction; by Sir George Newman on the teaching of hygiene in schools; and by Dr. H. M. Vernon and Dr. R. Cove-Smith on alcohol in relation to motoring and sport. Membership tickets, price 10s., can be obtained from the Secretariat, Room H, Imperial Institute, S.W.

The first international congress of gastro-enterology will be held at Brussels under the presidency of Dr. J. Schoemaker of The Hague from August 5th to 7th, when the subjects for discussion will be gastritis, and others, by Drs. A. F. Hurst, W. Zweig, Konjetzny, and others, and severe non-amoebic colitis, introduced by Drs. Gallart-Mones, Snapper, Lardennois, Donati, and others.

The eleventh annual conference of the Association of Special Libraries and Information Bureaux is to be held at Somerville College, Oxford, from September 21st to 24th. On the first evening with Sir Charles Sherrington in the chair, Sir Richard Gregory, president-designate, will give an address on "Science in the Public Press." The main discussion will be on "Book Selection for Special and General Libraries." The general secretary of the association is Miss E. M. R. Dittmas, M.A., 16, Russell Square, W.C.1.

The following German congresses will be held in the third quarter of the year: Ophthalmological Society, August 6th to 8th, at Heidelberg; 50th Congress of the Society for Children's Diseases, September 14th to 16th, at Brunswick; 93rd Congress of Natural Scientists and Doctors, September 16th to 20th, at Hanover; Society of Neurologists, September 27th to 29th, at Munich; Society for Industrial Diseases and Accidents, end of September, at Würzburg.

The Minister of Health has appointed an Advisory Committee to consider general questions relating to the administration of town and country planning in England and Wales, and any other related matters which may from time to time be referred by the Minister to the committee, and, as occasion may require, to make recommendations to him. The chairman of the committee is Mr. E. J. Maude, deputy secretary of the Ministry.

The Privy Council, in pursuance of the Pharmacy and Poisons Act, 1933, has appointed Sir Ernley Blackwell, K.C.B., to be chairman of the Statutory Committee of the Pharmaceutical Society.

The American Association for the Advancement of Science has awarded its annual prize to Dr. Reuben L. Kahn, assistant professor of bacteriology at the Michigan Faculty of Medicine and inventor of the reaction which bears his name.

The June issue of *Le Sud Médical et Chirurgical*, the monthly periodical published at Marseilles, is devoted to the surgery of childhood and orthopaedics.

The issue of *Paris Médical* for July 7th is devoted to diseases of nutrition.

Dr. Walter F. Richards of Reading, a member of the British Medical Association, and Mr. Reginald Droop, a medical student at St. Thomas's Hospital, are included in the crew of the *Endeavour*, challenger for the "America's Cup."

The Minister of Health has appointed Mr. C. F. Roundell, C.B.E., of the Ministry of Health, to be a member (vice Mr. N. B. Batterbury) of the Departmental Committee appointed in July, 1933, on the cost of hospitals and other public buildings.

The Italian Red Cross offers two prizes of 2,000 and 500 lire respectively for a monograph on morbidity and mortality from malaria in children in an endemic zone. The work should be sent to the Direzione della Croce Rossa, via Tuscania 12, Rome, before December 31st.

Dr. Friedrich von Müller, professor of internal medicine at Munich, has been nominated doctor *honoris causa* of the Geneva faculty of medicine.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Senile Pruritus

"VRACH" (Cornwall) writes: Can anyone suggest a fruitful line of treatment for an old lady, aged 76, pestered with senile pruritus? All the described remedies have been tried, more or less without result.

Tennis Elbow

"WESSEX" writes: Can anyone advise me on the treatment of the above condition, which I developed last May after a hard game of tennis? There is swelling and tenderness over the radio-ulnar joint, and pain on flexing forearm, and marked pain on taking a back-hand stroke. Treatment has consisted of firm bandaging over the affected part and the application of iodine.

Spermatorrhoea when Bathing

"M.D., D.P.H." writes: A friend has consulted me regarding his son, aged 21 years. This young man, who is in splendid health and excels at athletics, is unable to bathe, for immediately on entering the water he has an emission of semen. This is the first time I have met such a condition, and I should be grateful for any information as to cause and treatment.

Book Wanted

"W. G. R." would be most grateful if any reader would be prepared to dispose of a copy of Sutherland's *Dispensing Made Easy*. Leading medical booksellers state that the book is out of print.

Income Tax

Motor Car and Rent Allowances

"Glasgow" bought a car for £383 in June, 1929, and sold it in March, 1934, for £52, buying another for £115. He acquired a new practice on July 1st, 1933. The house is assessed at £80; one room is entirely set aside for consulting, and another large room and the hall are used two and a half hours a day. What deduction is due?

* On a 20 per cent. basis the car bought for £383 in June, 1929, will have depreciated to £157 at July 1st, 1933, and the allowance for the nine months to April 5th, 1934, will therefore be nine-twelfths of 20 per cent. of £157—that is, £23. For the year to April 5th, 1935, the depreciation allowance will be 20 per cent. of £115—that is, £23. As an expense of the twelve months to July, 1934, "Glasgow" can deduct the balance of the written-down value (£157—£23=) £134, less the amount received (£52)—that is, £82. With regard to the proportion of the assessment to be treated as a professional expense, one-half seems a little high—possibly £30 would be fair, but of course a lot depends on the actual circumstances.

General Expenses—Proportion

"M. S. R." explains that there is whole-time use of a consulting and a waiting room, and casual use of a drawing room; in addition, a garage has recently been erected—though it is not stated whether the Schedule A assessment has been increased to cover the addition. One maid is kept, and in her absence the practitioner's wife has to assist.

** It is always difficult to suggest a reasonable ratio where so much depends on circumstances. One-half of the general expenses and one-third of the heating and lighting would seem to be a maximum, and would perhaps be somewhat generous. No deduction can be claimed for the wife's services unless she is actually paid for them.

LETTERS, NOTES, ETC.

Asthma in Childhood

Dr. A. W. DOCKAR (Birmingham) writes: I note with interest the letter by "G. P." (Surrey) on this subject (July 7th, p. 48). I do not think he has cause to be too much dismayed by the result of his treatment. Factors, little understood, still confront us. The results of autogenous vaccine, in my experience, have not been too convincing. They would seem to increase the patient's resistance to infection, but their effect on the "asthmatic diathesis" is questionable. From a series of investigations over a number of years I find that, in the differential leucocyte count, the eosinophil percentage tends to fall during the winter season and to rise during the summer, and more so if the summer be warm and dry for long periods such as we are experiencing now. These variations seem to take place in spite of medicinal and autogenous vaccine therapy, and the inevitable result of a rise in the eosinophil percentage is increased liability to an asthmatic attack. It would seem to me that, in these cases, one is dealing with constitutions biochemically imbalanced and incapable of normal self-adjustment to certain internal and external influences. From investigation of family blood readings I am convinced that this fundamental state is congenital, not acquired—that is, the child derives a familial tendency which, unfortunately, is not often recognized clinically till typical asthma has developed. Perhaps a little more attention to this pre-asthmatic aspect of the subject, with a view to adopting preventive measures early, would prove of inestimable value. In the case of children the asthmatic attack has often prodromata, such as languor, gastric disturbance, etc., readily recognized by intelligent parents. To aid in aborting an attack I immediately recommend an effective purge, followed by total restriction of food for twenty-four hours. Copious draughts of water are given during that period. This seems to give the child a chance of regaining its "metabolic balance," if I should dare to use such a term. Afterwards diet is gradually resumed. I am indebted to Dr. James Adam of Glasgow for much valuable help gleaned from his book on asthma.

A Warning

Messrs. E. H. WEEDON AND CO. (Bow Road, E.3) inform us that an agent recently in their employ, aged about 55-60, has been calling on medical practitioners and veterinary surgeons asking for loans of money (usually 2s. or 2s. 6d.). At present his activities are mostly confined to East and South-East London and Essex.

Corrigenda

In last week's issue, under the heading "Test for Live Birth" on page 142, the word "Fagerlung" should have read "Fagerlund."

The review of *Modern Treatment in General Practice*, published last week at page 118, stated that this book consists of fifty-three chapters; there are in fact fifty-six chapters.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 32, 33, 34, 35, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 36 and 37.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 84.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, AUGUST 4th, 1934

ARE WE SATISFIED WITH THE RESULTS OF ANTE-NATAL CARE?*

BY
JOHN S. FAIRBAIRN, M.A., B.M., B.CH.OXON, F.R.C.P., F.R.C.S., P.C.O.G.
CONSULTING OBSTETRIC PHYSICIAN, ST. THOMAS'S AND GENERAL LYING-IN HOSPITALS

The question forming the subject of this discussion comes at an opportune moment, although it can admit of a negative answer only, as finality in progress is unthinkable. At the same time we have no grounds for complacency. For twenty years or more ante-natal care has been vaunted as the sovereign remedy for the static maternal death rate, which, however, obstinately refuses to respond to treatment. Hence, I take it, our object is to review our ante-natal work and to see where its weaknesses lie, and the task I have set myself is to re-state its aims, the attitude of mind in which it should be approached, and the principles underlying its practice. Clinical details I leave to my obstetrical colleague.

Midwifery a Branch of Preventive Medicine
The ante-natal clinic deserves much of the credit for the impulse leading up to a general recognition of "midwifery as a branch of preventive medicine," a slogan that had a wide vogue for a time, although it is clear that all it implied was not understood and certainly not acted upon. My interpretation of preventive medicine translated into clinical practice is that the promotion of health and normal working in all systems of the body becomes the primary objective. In midwifery, where the reproductive function in women is our charge, our first and chief duty is to learn what can be done by constructive physiology—that is, the adoption of measures tending to promote normal function throughout the processes of reproduction. After this comes the "preventive" part, strictly speaking, the removal or correction of possible causes of interference with physiological action. Lastly comes the watch for early evidence of disordered function and the effort to restore the normal before more serious or permanent trouble arises—for example, the testing of urine to discover albuminuria and the conditions underlying it.

Thus in successive stages we pass from constructive physiology through prevention to what may be termed, by antithesis, "destructive pathology." My point is that the first and constructive stage has not been fully understood and accepted as the primary purpose of the supervision of the expectant mother; often the two later stages are alone considered. About a year ago I noticed a letter in the *Lancet* in which this aspect was put so clearly that I venture to quote the words most appropriate to ante-natal clinics, for the letter was not prompted by them, but by a proposal for the periodic examination of women to discover the early stages of uterine cancer before symptoms arose. The writer of the letter, in setting out his objections to that suggestion, said:

"Our own generation, however, seems to have more fear of disease than love of health; we ourselves are not free from

the belief that it is our sole function to search out abnormalities, to declare them and to correct them if we can, and we are still far from the day when the reproach of having imagined a pathological condition will be esteemed as great or greater than the reproach of having overlooked one."

This quotation sums up the incorrect perspective in which much of our ante-natal work is viewed. The search for trouble is too much in the foreground, and constructive hygiene too far in the background. Hunting for signs of the abnormal results in the most being made of minor deviations from the mean, and often without proper consideration being given to the reserve power of mother nature. Here will be a misfit that must be beyond the natural powers, or there a cardiac or other medical complication that must prove fatal unless Caesarean section is performed or abortion or premature labour induced. It is generally accepted that intervention for hypothetical trouble has been grossly overdone, and a material proportion must be ascribed to misunderstanding the purpose of, and to misdirected zeal in, the conduct of ante-natal supervision.

More than lip-service is needed before midwifery is, in fact, "a branch of preventive medicine." The whole practice of midwifery, and particularly ante-natal work, must live up to the principle that its primary aim is the attainment of normal function. Once this ideal permeates completely the ante-natal period it will leaven the whole.

Study of the Individual

The next point I will emphasize is the importance of full consideration being given to the individual woman, mind as well as body, her circumstances, and her reactions to them. She is too frequently regarded as if she were a cow, and had no thought of what pregnancy, labour, and the rearing of her progeny involved. There is too much veterinary practice in obstetrics as well as in general medicine and surgery, and, in these days particularly, when there is much more talk in the vulgar tongue of problems of sex and reproduction, the reaction of the expectant mother to pregnancy and all it means to her is given too scant attention. In the textbooks there is a learned discussion of her biochemical reactions, normal and abnormal, but little or nothing of her mental responses. She may be distracted by an unwelcome pregnancy and desire its interruption, or she may be overjoyed that a long-hoped-for pregnancy has come but obsessed with fears of its premature ending or of disaster to the foetus. Or again, she may be full of dread of what is before her, or terrified by stories of what she has heard from others; or she may, like the cow, have given no thought and worried not at all as to what is in front of her. But all women should not be treated alike, as if they were cows and without imagination. Our ante-natal supervision has not as yet enabled us to predict a natural delivery for a healthy well-formed

* Read in opening a discussion at a joint meeting of the Sections of Obstetrics and Gynaecology and Public Health at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

woman with a normal presentation and position. She may take a day or more, and in the end be delivered artificially. This result may be accepted as next door to a natural delivery, but surely we should not be satisfied with second best, but should seek some means of improving the final expulsive efforts whereby the frequent resort to artificial methods may be avoided. This problem has scarcely entered into the philosophy of ante-natal care, although it is now generally agreed that the largest factor in the failure to complete expulsion is the emotional effects of anxiety and fear and the early fatigue that follows in their train. More attention is now being paid to this aspect of ante-natal work, but by general practitioners rather than by professed obstetric specialists, and several books⁴ and papers have recently appeared stressing the importance of the psychic factor during pregnancy and labour.

In the individualization of the pregnant woman must be included also the social and educational work that forms an essential portion of the ante-natal care in all classes of the community, and calls for modification to suit the character and special circumstances of each patient. It is well done in the public ante-natal clinics, and in those hospitals with a social service department, in both of which there are officers specially detailed for the duty of home visiting and inquiry; but it is liable to be overlooked in private practice⁵ and in smaller institutions.

Thoroughness and Continued Observation

The next point to be emphasized is that the supervision of the pregnant woman must be thorough and continued. The fault does not seem to me to lie so much in the medical and obstetrical examination as in the less obvious aspects already referred to, and in the failure to resort to continued observation in hospital or nursing home of cases showing slight or early signs of departure from the normal. The gravity and meaning of slight losses of blood during pregnancy, of vomiting that does not yield to simple remedies, of minor degrees of albuminuria or rise of blood pressure, and of many general diseases complicating pregnancy cannot be accurately estimated unless the woman is under medical observation and watched by competent nurses. Occasional visits to a clinic or medical attendant do not afford a satisfactory basis for a prognosis or judgement on the effect of treatment. But either from lack of facilities or failure to recognize the need for closer observation many disorders in an early stage are allowed to become serious before correct treatment is begun.

Unity in Purpose and Method

Reference to those sadly overworked words "co-ordination" and "co-operation" cannot be avoided, because ante-natal care calls for varied forms of service from various types of worker and for close contact between all of them, and unity in purpose and method are largely contributory to its effectiveness. Ante-natal supervision is so integrated with the rest of midwifery practice that it cannot be separated off without the efficiency of both the part and the whole suffering greatly. Its segregation in the public ante-natal clinics has been open to obvious criticism on this score, though the policy was more or less forced on the local health authorities by the Act of 1918. The result has been that the country has never received a proper return for the money expended on these clinics, a fact which seems to have struck the officials in Whitehall, judging by their memoranda advocating a co-operation so effective as to overcome all drawbacks to an ante-natal supervision exercised by those who have no concern with the mother during labour and lying-in. The merit of team work and a certain degree of uniformity in practice, our large maternity hospitals are not free from a lot of criticism: there is one member of the staff for the pre-

natal, another for the intra-natal, possibly a third for the post-natal care of the mother, and certainly another for the mother and infant in the infant welfare clinic. Reports between these different members of the staff cannot wholly compensate for the personal touch, and the influence that goes with it, when the woman is throughout under the same charge. The effort should be made to maintain responsibility for each patient in the same hands at least from pregnancy until mother and infant are passed to the infant clinic.

For these reasons the family practitioner is the ideal supervisor of the mother and her infant throughout reproduction, but, if he is to fulfil his part adequately, he must have assistance from a midwife, working under his direction to undertake the observational, educational, and mothercraft services given by health visitors, social workers, and other officers in hospitals and public clinics. The British Medical Association scheme to delegate this part of the work for insured patients to the public clinics does not appeal to me because of the division of responsibility and the loss of personal influence thereby entailed.

In conclusion, I trust the emphasis I have laid on the attainment of the physiological as our primary aim will not be taken as lessening the need for observing signs of departure from the normal. I have tried only to correct the perspective.

ARE WE SATISFIED WITH THE RESULTS OF ANTE-NATAL CARE?*

BY

F. J. BROWNE, M.D. ABERD., D.Sc., F.R.C.S. ED.,
F.C.O.G.

PROFESSOR OF OBSTETRICS AND GYNAECOLOGY, UNIVERSITY OF LONDON, AT UNIVERSITY COLLEGE HOSPITAL, LONDON

Dr. Fairbairn has referred to the influence of the emotions in pregnancy and childbirth, and we shall probably all agree that in our enthusiasm for the development of the preventive side of obstetrics we have occupied ourselves too exclusively with mechanistic conceptions of the physiology of labour and with mechanical measures for meeting the difficulties encountered. It is worthy of note, also, that the late Dr. Ballantyne, in his last address in 1923, in which he set out clearly the benefits that he expected would follow ante-natal care, put in the forefront "the removal of anxiety and dread from the minds of expectant, parturient, and puerperal patients; and the removal of much discomfort amounting in many cases to suffering."

It is a matter of some historical interest that Ballantyne was originally led to advocate ante-natal care, not for the sake of the mother at all, but in order that we might be enabled thereby to discover the causes of, and to prevent, monsters. This we can easily understand when we recall that his two volumes on *Ante-natal Pathology* had been published in 1904, and that all his work and interest up to that time had been concentrated upon foetal pathology. It was only much later that he came to see that other gains might follow, such as reduction of the maternal death rate and of the number of stillbirths and neo-natal deaths.

* Read in opening a discussion at a joint meeting of the Sections of Obstetrics and Gynaecology and Public Health at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Effect of Ante-natal Care on Maternal Mortality

TABLE I.—Incidence of Maternal Deaths from Puerperal Albuminuria and Convulsions

It will be seen that while up till 1930 the death rate from eclampsia remained unchanged, in the last two years for which figures are available there is a distinct reduction. Yet, considering that eclampsia is almost entirely a preventable disease, the incidence and death rate are still far too high. One county medical officer writing to me recently confirms this. After saying that it is the exception now for the expectant mother in his area not to receive ante-natal care, he continues:

"Yet it must be admitted that it has not so far resulted in any reduction in the maternal mortality in the area . . . one conspicuous cause has been eclampsia. It is strange that the operation of a scheme which might have been expected *par excellence* to have eliminated or at any rate substantially reduced the incidence of eclampsia has not so far done so."

I may say here that it would be an important step forward if eclampsia were made a notifiable disease. We should then have valuable information as to its geographical distribution, regarding which we know next to nothing at the present time.

This, then, is what ante-natal care has accomplished. All will agree that we cannot be satisfied with the results so far obtained. The remainder of this paper will be occupied with an inquiry into the reasons for this comparative failure.

TABLE II.—Percentage of Primiparae and

Increased Frequency of Primary Births

If it could be shown that there has been in recent years an increase of primary as compared with subsequent births, such increase might be assumed to have a more or less important influence in neutralizing any improvement in mortality rates that would otherwise have followed ante-natal care. We should, of course, expect such an increase in primary births because of the fall in the birth rate, but apparently no statistics on this matter exist. I have therefore tried to collect information from the Ministry of Health, county medical officers of health, and other sources, but with one or two exceptions the replies were to the effect that they possessed no information. The chief exceptions were the West Riding of Yorkshire, Monmouthshire, and the City of Manchester, and Table II shows the figures obtained from these and one or two other sources.

These figures, I think, leave no room for doubt that the frequency of primary births has been steadily increasing for twenty years. As eclampsia is a difficult labour

These figures, I think, leave no room for doubt that the proportion of primary births has been steadily increasing during the past twenty years. As eclampsia and accidental haemorrhage, as well as difficult labours, are more common in primiparae it may be assumed that here we have an important factor in maintaining the high death rate. It is to be noted, however, that the mean age of marriage in females is the same now as forty years ago—namely, 26.

Much Ante-natal Care Inadequate and Ineffective

About 42 per cent. of all parturients in England and Wales are looked after at State-aided clinics. Midwives, too, who attend about half of all the labours in the country, are required by the Central Midwives Board to give ante-natal care to the patients booked by them, and to keep records. Then there is the care given by hospitals and by private doctors. Taking the country as a whole it is probably correct to say that quite 80 per cent. of expectant mothers now receive ante-natal care of some kind or degree. Many of the most elaborate schemes, however, have only been in existence for a year or so, and could not therefore have yet affected mortality returns. In one county, for example, there are now thirty-four clinics as compared with six three years ago. Judging as these figures are I believe that much ante-natal care is inadequate and ineffective. All who have

or so, and could not therefore have been so effective. In one county, for example, there are only four clinics as compared with six three years ago. Imposing as these figures are I believe that much antenatal care is inadequate and ineffective. All who have to do with this work know how easy it is to become slipshod because abnormalities are comparatively rare. In no department of medicine is one so liable to drift into careless ways and thus miss the occasional abnormality or the occasional early sign of impending danger, and against this the ante-natal worker needs to be constantly on guard. Munro Kerr¹ has emphasized this. He says: "It is watchful care that is essential. . . . The constant watchfulness on the part of those in attendance tends to slacken as in so many cases nothing abnormal occurs."

[illegible]

Area	1913	1915	1920	1922	1923	1924	1925	1926	1927	1928	1929	1930	1931	1932	1933	Total Cases Analysed

Much of that which now passes under the guise of ante-natal care is unworthy of the name. Examinations are too infrequent, perfunctory, and unskilled to accomplish anything useful. I have previously shown,² for example, that many clinics in teaching hospitals are doing nothing to reduce eclampsia among their own cases, for its incidence in the booked patients attending is as high as in the general population, and yet we know that eclampsia is almost entirely a preventable disease, and that in a few clinics it is being prevented. If this is happening in our training schools can we expect better at the hands of the general practitioner or midwife? Writing to me on this matter one medical officer said: "I am of opinion that the ante-natal work at the institutions with which I am acquainted is extremely badly done. Far too much is undertaken by the resident medical staff, and the consultants are rarely called in."

It is time we realized that ante-natal work calls for experience and skill, that patients must be individualized in regard to diagnosis and treatment, and that in ante-natal work there should be no such thing as mass production. The success of a clinic should be judged, not by the numbers passing through its books nor even by the number of attendances registered by each patient, but by its effect in reducing maternal mortality. It would be a great advantage if all medical officers gave such information in their annual reports as some already do. None of us are exempt from mistakes and failures, but each failure or mistake ought to be an occasion for self-examination and possibly for an overhaul of present methods.

Concerning the quality of the work done by midwives it is difficult to get information. Some of it may be fairly good, especially as they have to keep records and their work is more or less supervised. The standard of entry to the roll of the Central Midwives Board is, however, deplorably low, and only 10 per cent. of those entering for the qualifying examination are rejected. Surely the lowest standard of any examination in this country! Besides, they are handicapped by their inability to estimate blood pressure, a rise of which is often the earliest sign of pre-eclamptic toxæmia, and may precede the appearance of albumin in the urine by several weeks. Is it too much to hope that all the midwives of the future may be trained in the estimation of blood pressure, and that public health authorities may consider it worth while to provide them with a simple form of blood-pressure recording apparatus? One medical officer writes me that his council provides midwives with callipers with which to take pelvic measurements. I believe the callipers to be a useful and necessary instrument, but even more necessary is a manometer. I might add that some medical officers sent me copies of the record forms which they had drawn up, and which the practitioners working under the local scheme were required to keep. None had any place for recording blood pressure, and this in spite of the fact that in the minimum scheme for ante-natal examination circulated by the Ministry of Health the importance of such a record was clearly pointed out.

It is the custom nowadays to belittle the whole-time clinic officer. It is usually laid down that the person responsible for the delivery should look after the woman in pregnancy, and there can be no doubt that, other things being equal, this is desirable. Yet there is much to be said for such officers. They are usually extremely keen, and nowadays they must have had post-graduate experience of maternity work, though judging from advertisements still appearing in the medical press this regulation is more honoured in the breach than in the observance. They are less likely to be hurried than the general practitioner; they can devise a follow-up system to ensure

regular attendance, and as they see more patients than any individual practitioner they should become more highly skilled in diagnosis. Their work suffers, however, both in interest and in usefulness, from the fact that they are not allowed to give treatment, and one medical officer expresses the opinion that attendances at clinics would be much higher if treatment were given. Of course, effective ante-natal treatment often means institutionalization, but since much greater facilities for this are necessary it should be possible to arrange for the patient to be admitted under the care of the medical officer who has looked after her in the clinic. This would mean the addition of facilities for delivery, but I believe that these will in future be found to be a necessary provision, for the time is surely coming when none but normal midwifery and, perhaps, low forceps cases will be undertaken in the patient's own home.

Keen and competent whole-time clinic officers are often discouraged by the indifference of practitioners to whom they refer patients for treatment, and I know personally of cases of this sort. One county medical officer states that the ante-natal clinics were at first run by general practitioners,

"but they were so indifferent we had to appoint whole-time officers in charge. The whole-time system is becoming increasingly popular with midwives and mothers. It has been our custom to inform the doctor of the proceedings at the clinics and to invite co-operation, but it is so infrequent that my officers get any replies to their notes that I can only assume that general practitioners are not interested in this work."

This gap between diagnosis and treatment is to my mind a very serious one, and calls urgently for consideration.

Unnecessary Intervention in Ante-natal Care

Induction of premature labour and Caesarean section at term for disproportion are good examples, and no one will deny that much of this intervention is unnecessary or that in most cases delivery would have taken place without trouble had the patient been left alone. It would be a simple matter did space permit to prove this from the reports of leading hospitals, and Wrigley,³ in a recent paper, has already done so. This intervention would not matter if these operations were always safe, but we know they are not. I need only mention that in their last published reports eight teaching hospitals in this country record forty-four deaths among their own booked cases, and of these twelve (27 per cent.) followed Caesarean section in originally "clean" patients, the most frequent cause of death being general peritonitis. I believe I am justified in saying that ante-natal care has often simply transferred mortality from one column to another. Deaths from obstructed labour are now comparatively rare, but we have replaced them to some extent by deaths from preventive operations. The remedy lies in the realization that even the best ante-natal care does not abolish the need for good obstetrics, and that it may even be dangerous unless supplemented by wise conservatism in treatment.

Increased Demand for Intervention, Anaesthetics, etc.

Fairbairn⁴ has pointed out that in 1924 and 1925 there was evidence of an increasing tendency on the part of the Queen Victoria Jubilee Midwives to send for medical aid during labour. During 1924 in 13 per cent. of cases the doctor had been called in on account of difficulty or delay. In 1925 the frequency had risen to 17.9 per cent. I have obtained the figures for 1931, 1932, and 1933, and they are 20.1, 22.1, and 21.5 per cent. respectively. Are we to put this down, as Fairbairn does, to the midwife

AUG. 4, 1934]

ARE WE SATISFIED WITH RESULTS OF ANTE-NATAL CARE?

THE BRITISH MEDICAL JOURNAL 197

becoming less self-reliant, or may it not be due to a decreased capacity to bear pain and to an increasing demand for rapid termination of labour and especially for anaesthetics?

Finally, we should not forget that there is a certain proportion of obstetric complications that ante-natal care is so far powerless to prevent. These have been recently analysed by Strachan,³ and to his paper I shall refer those interested.

I would end on a note of hopefulness. Disappointing as have been the results hitherto we are in the mood for self-criticism, and this may be the prelude to a fresh advance. A conference such as this between two of the Sections most nearly concerned in the success of ante-natal work cannot but result in a fresh integration of effort. And in the words of Walt Whitman: "It is provided in the nature of things that from any fruition of success shall come forth something that shall make a greater effort necessary."

ARE WE SATISFIED WITH THE RESULTS OF ANTE-NATAL CARE?*

BY

ETHEL CASSIE, M.D., D.P.H.

ASSISTANT MEDICAL OFFICER OF HEALTH AND CHIEF MEDICAL OFFICER, CHILD WELFARE, BIRMINGHAM

There is a deceptive simplicity about this question to which we have been asked to furnish a reply. It seems at first sight to require little more than a confirmatory "Yes" from those of us who have been enthusiastic advocates of the provision of ante-natal care. Further consideration, however, shows that the question covers a very wide field, and no such simple confirmation is quite possible. It becomes necessary, indeed, to put two further questions: (1) What is meant by ante-natal care? ; and (2) What results can be expected from it?

It is only by defining in some measure what ante-natal care has meant that we can judge the results which have been obtained. It is obviously useless to feel disappointed with a remedy which has never been properly applied. There is actually an official standard for ante-natal clinics set out in the circular 145/M. & C.W., issued by the Ministry of Health in 1929. This standard was not put forward as an ideal but as a practical minimum for effective usage, and I feel sure there will be fairly general agreement when I say that a high proportion of women receiving ante-natal care, whether at ante-natal clinics or elsewhere, do not receive it at this minimum standard. This may be due in part to faults of administration or to faults in doctors or midwives, but it is also, to a great extent, undoubtedly due to the women themselves, since even when facilities are available and are freely offered full advantage is not taken of them.

Ante-natal Care in Birmingham

We have, I believe, reached the point at which a demand for a high standard of ante-natal care can and will be met, and I feel sure—indeed, there can be little

* Read in opening a discussion at a combined meeting of the Sections of Obstetrics and Gynaecology and Public Health at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

doubt about it—that such a demand will shortly become universal. This suggestion is supported by the rapidly increasing number of women who present themselves at the ante-natal clinics, and in this connexion the records of Birmingham are of interest. Birmingham first formally opened its ante-natal clinics in 1916. During that year 250 were held, and 561 women attended. Eight years later, in 1924, the clinics had increased to 931, and 4,043 women attended. In 1932 the figures were 1,892 clinics and 8,174 women attending. Meanwhile, the births had fallen from 21,347 to 17,219. A very high proportion of the births are visited by health visitors, and taking these as representing those women who are invited to ante-natal clinics, it will be seen from the table supplied that in 1932 no less than 50 per cent. had attended the clinics.

TABLE I

	1916	1924	1932
Number of ante-natal clinics at child welfare centres	250	931	1,892
Number of mothers attending ...	561	4,043	8,174
Total attendances made ...	No record	10,395	25,933
Births (including stillbirths) ...	21,347	18,934	17,219
Births visited (not including stillbirths)	8,143	15,957	16,180
Percentage of mothers attending from the visited class (approx.)	6 per cent.	25 per cent.	50 per cent.

This represents only a portion of the amount of ante-natal care given and received: taking into account the work of the family doctor, the midwife, and the maternity institutions, it is obvious that the total must be considerable. There can also be little doubt that the standard is as high as anywhere in the country, though space does not permit of a detailed description. As regards the ante-natal clinics, the arrangements for following up and co-operation are fairly complete, and the work is carried out by experienced medical women with every facility for consultation and with sufficient available ante-natal beds.

And yet one is forced to believe that the standard is not sufficiently high in a large proportion of cases. The average attendance per patient in 1932 was three, and when one considers that many women pay from five to eight visits it is clear that numbers pay only one visit. The midwives, although informed when their patients cease to attend ante-natal clinics, cannot, as a general rule, give really effective supervision at the standard laid down in the Ministry's memorandum. They have not the facilities, and the patients are often not very amenable. The lack of sufficient ante-natal care is frequently recorded in relation to stillbirths, deaths in childbirth, and puerperal sepsis investigations.

Ante-natal supervision might be expected to affect maternal mortality in childbirth, neo-natal mortality, and the stillbirth rate. There has been no material improvement in these rates since 1916.

TABLE II

Birmingham	1916	1924	1932
Maternal mortality ...	3.4	3.91	3.73
Neo-natal mortality ...	34.4	41.9	32.7
Stillbirths ...	3.5	2.9	3.6

During the last five years every maternal death in childbirth in Birmingham has been investigated as carefully as possible and an attempt made to assess the influence of ante-natal care (Table III). In the deaths from intercurrent disease in this group fifty-seven out of eighty-

Total ...	17	20	37	62	19	16	98	19	61	88	12	52	61

Total deaths = 396.

seven women had not received adequate ante-natal care. In fatal abortions thirty-five out of sixty-two were probably associated with "interference." In nineteen of the ninety-eight deaths from sepsis ante-natal care had failed to give the help that should have been given, and in sixty-one it was insufficient. In the toxæmias no fewer than sixty-four out of the eighty-eight cases had had too little ante-natal care or none at all. In the group collected as "other causes," including ectopic gestation, Caesarean section, etc., no assessment has been attempted. The general inference to be drawn from these figures is that in a large proportion of cases, while death could not directly be considered as due to failure of ante-natal care, there was no doubt that the standard and amount was altogether insufficient for the minimum of efficiency.

Findings in a Maternity Home

I have endeavoured to show, then, that if ante-natal care has not succeeded in lowering maternal mortality in Birmingham it has not had a fair chance of doing so. In the history of the fatal cases its absence or insufficiency is prominent. The consideration of what happens where the standard is satisfactory is worth studying in contrast, and for this reason the findings at one of the city maternity homes are recorded:

The ante-natal work in this home is of the highest standard, and the women are required to submit to every requirement of the medical officer, or their "booking" is cancelled. Therefore it can be taken that the results reflect the best that intensive ante-natal care can secure. The only selection from the medical point of view is that Caesarean section cases are not booked, and that inevitable early inductions are excluded. The figures have been taken from 1,000 consecutive booked cases delivered in the home, of which 56 per cent. were primiparae and 44 per cent. were multiparae. Seven hundred and thirty-nine patients, or 74 per cent., were normal throughout pregnancy and confinement, and the remaining 261, or 26 per cent., were admitted for treatment to the ante-natal ward. Some of the conditions found, such as heart disease, pyelitis, and toxæmia, required prolonged treatment.

We have here a very low maternal mortality rate, 1 per 1,000, which was the same as in the previous 1,000 cases delivered in this home, but it must be remembered that abortions, intercurrent disease, and the group classed as "other causes"—that is, ectopics, etc.—are excluded. The stillbirth rate remains practically unaffected as compared with the city as a whole. The neo-natal mortality is improved, but this is undoubtedly due to intensive and highly skilled care of the premature infants, the proportion of which is increased by the frequent inductions. The city neo-natal mortality for the first fortnight of life is

TABLE IV.—*City Maternity Home (1,000 Consecutive Booked Cases)*

(Primiparae = 56 per cent. Multiparae = 44 per cent.)

Normal throughout, 739 = 74 per cent.

Complications of pregnancy—admitted to ante-natal ward, 261 = 26 per cent.

Maternal mortality = 1 per 1,000.

Stillbirth rate = 3.3 per cent.

Neo-natal mortality = 1.6 per cent.

Complications	No. of Cases	Results

Total	261	—	—

28.3 per 1,000 births in comparison with 17 per 1,000 births in the home. At the same time, no one can study this table without realizing the importance of ante-natal examination and treatment from the point of view of the 26 per cent. abnormal cases.

Present Position Reviewed

It seems clear from the conditions found that not only is ante-natal care essential, but also that the obstetrician making himself responsible for it should be as much a physician as a surgeon. The tendency to combine obstetrics and gynaecology has led to the importance of the physician's point of view in the care of the expectant mother being overlooked to some extent. If that happens ante-natal diagnosis and treatment will never be satisfactory. A great deal is heard of the importance of the

AUG. 4, 1934]

ARE WE SATISFIED WITH RESULTS OF ANTE-NATAL CARE?

THE BRITISH
MEDICAL JOURNAL 199

ante-natal clinician knowing what happens at the confinement, but it is even more important for him to recognize what is happening to the patient before the confinement. Until ante-natal care includes the careful study of the patient as a whole and throughout pregnancy it will be impossible to say that we are satisfied with the results it gives.

At present one is far from satisfied, but that simply means one remains dissatisfied with the amount and standard of ante-natal care. As far as can be judged, where the standard is satisfactory, one can hope to obtain a marked decrease in maternal morbidity, with an incalculable improvement in the health of the mothers, and a definite reduction in maternal mortality when combined with really skilled obstetrics. The effect on the stillbirths and neo-natal deaths remains in doubt. Fewer cranial injuries, certainly, but probably more premature babies from inductions, may result. This suggests that skilled and prolonged treatment and care of the infant is essential, and ante-natal care may benefit the mother even more than the child.

At the same time not ante-natal care alone, but all the influences at work to raise the health standard of the nation must benefit women and ultimately their infants. With the disappearance of rickets, and with better nutritional standards for children and adolescents, pregnancy and childbirth should become less dangerous to both mother and child. Among the helpful factors is the universal realization of the importance of prevention and the value of careful medical supervision during pregnancy. There are factors, however, which delay progress, and among these the inadequate training of the medical student and midwife in all that concerns obstetrics and infant care is the most serious. While there has been great progress in recent years, this has not gone far enough, and there can be little doubt that the best use is not being made of the available teaching material. The teachers are frequently too few, and only too often overworked. Expediency and improvisation are still advocated before efficiency. Ante-natal care will not fail to give satisfactory results when knowledge, careful observation, and unceasing vigilance are used to benefit every expectant mother.

The final position of the ante-natal clinic at the child welfare centre is problematical. It is generally agreed that the routine care of the pregnant woman should be in the hands of those who will attend her during labour. Whether the present tendency to enter institutions will go further, or whether the district midwife and the general practitioner will retain their present predominance in this field, remains to be seen. In either case, with the progress of medical education and the better training of midwives, the position of the clinics must alter. They may become consulting clinics, or they may serve as outlying clinics for central institutions. Their present role is that of pioneers, and their task predominantly educational. While the position to-day is not altogether satisfactory, we can say of ante-natal work, in the well-known phrase, that it is progressing as well as can be expected!

The Child Guidance Unit at the West End Hospital for Nervous Diseases (73, Welbeck Street, W.1) began work in October, 1932, and a report for the year 1933 by the honorary director (Dr. Emanuel Miller) has lately been issued. The special feature of this unit is that it is established in a voluntary hospital, and makes provision for in-patient observation and treatment, as well as for sessions held in special quarters in the out-patient department. All cases are seen in the first instance by a neurologist on the staff of the hospital, thus eliminating organic diseases and other unsuitable cases.

ARE WE SATISFIED WITH THE RESULTS OF ANTE-NATAL CARE? *

BY

GEORGE F. BUCHAN, M.D., F.R.C.P., D.P.H.
MEDICAL OFFICER OF HEALTH FOR WILLESDEN

Ante-natal care was begun in this country about the beginning of the present century. It is now generally accepted as an integral part of the care of maternity, but no standard is yet in universal operation. The Maternity and Child Welfare Act was passed in 1918, and since that time ante-natal work has considerably expanded. Nevertheless, the general maternal mortality rate per 1,000 live births does not show any material change since that date. Maternal mortality is in part due to lack of ante-natal care, and the absence of any fall in the rate probably means that the ante-natal care given in many places is still insufficient.

Ante-natal care has the following objectives: (1) to maintain the health of the pregnant woman; (2) to secure delivery with the least possible disturbance to the pregnant woman; (3) to secure for the child an adequate supply of breast-milk during the normal period of lactation. The questions that arise are: (1) how can we secure these objectives; and (2) to what extent do the methods generally in use fall short of the best? Ante-natal care, so far as the mother is concerned, includes the problem of the maintenance of her general health and nutrition, and her obstetric state.

Attention to the general health and nutrition of the mother involves a knowledge of her home surroundings, food, habits, work, and recreation, as well as a careful and systematic physical examination. These two factors—namely, the environment of the patient and her general physique—have to be carefully correlated, and advice should be given by a medical practitioner competent to do so as to any measures, social or medical, which are necessary to improve the patient's general hygiene. The home environment should be reported not only by the doctor but also by a health visitor. In order that the patient may be in a position to safeguard, and to improve if necessary, the mother's health, one consultation during pregnancy is not enough. This supervision should be carried out at regular intervals at appointed times. The failure of the mother to attend on any specified occasion should be followed up immediately by an inquiry at the home as to the reason for her non-attendance. This provision for ante-natal care is important, since it is not infrequently the case that the pregnant woman has failed to keep her appointment on account of her physical condition, which may urgently require treatment.

Ante-natal Work and Subsequent Confinement

The next point that arises concerns the obstetric state of the patient. A special physical examination of the mother is required to ascertain the condition. The Ministry of Health, in its regulations of 1930, has laid down that medical officers in charge of ante-natal clinics are required to possess special experience in practical midwifery and ante-natal work. The importance of the association of practical midwifery with ante-natal work is thus recognized, and I am convinced that, if the best results are to be obtained from these obstetrical examinations, they must be linked up with the subsequent confinement. It is impossible for an ante-natal medical officer

* Read in opening a discussion at a combined meeting of the Sections of Obstetrics and Gynaecology and Public Health at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

materially to enhance his experience unless he is in a position to check his diagnosis and prognosis by the happenings at the confinement itself. A paper report by another practitioner is insufficient for this purpose, and is an unsatisfactory alternative to attendance at the confinement.

Having thus secured the ante-natal care of the pregnant woman it is necessary to consider the confinement, so that there may be a minimum of disturbance to the patient. The obstetrician who has been responsible for the ante-natal supervision should take charge of the confinement. I am aware that there are different schools of thought as to the management of different varieties of complicated labour. It is not my province to discuss these, but it is my concern to know that the practitioner undertaking the management of the labour should be fully aware of its possibilities, and fully equipped and experienced to deal with any eventuality.

In order, therefore, that the foregoing conditions may be met, the following propositions are submitted:

1. That the general health of the expectant mother should be under the care of a medical practitioner competent to carry out not only medical examination, but also to advise as to the hygiene of pregnancy from both the social and the medical aspects.
2. That these consultations should take place regularly throughout pregnancy, and failure to keep an appointment should be inquired into without delay.
3. That the obstetric examinations made during the ante-natal period should be carried out by the obstetrician who will be in charge of the confinement, and who should have sufficient experience to cope with any abnormality, whether foreseen or not.
4. That hospital beds should be available for all ante-natal cases requiring such accommodation.

Where Present Methods Fail

These being the conditions which, in my opinion, should govern ante-natal care, it is necessary next to ask how far the present methods of ante-natal supervision comply with the propositions here set out. I think it may be fairly said that, so far as the work of local authorities is concerned, attention to the general health of the pregnant woman is given by a doctor, generally speaking, competent to do so from both the medical and the social aspects, although it may be doubtful if sufficient emphasis is always laid on the basic need for the adequate nutrition of the patient. Unfortunately, it is not always the case that women who fail to keep their appointments are immediately followed up to ascertain the reason for their non-appearance. If the reason is not connected with their health, it may be that no harm is done, but in many cases, especially towards the later weeks of pregnancy, failure to keep an appointment is often due to the physical state of the mother, which may require immediate attention, including her removal to hospital.

It is true that where the general health of the mother reveals some abnormality associated with the pregnancy—for example, albuminuria, or a complication of her general health—as, for example, heart disease—a hospital bed is not always available. Further, she may be unable to leave her home because she cannot make provision for its continued care during her absence, which in some cases may be prolonged. Ante-natal beds are also needed during the ante-natal period on account of the obstetric condition, and these again are not always available.

It is further the case that in only a limited number of instances is the obstetrician responsible for the confinement associated with the ante-natal work of local authorities. To my mind, where this association does not exist, the value of ante-natal care is very materially diminished. No matter how expert an ante-natal medical officer may consider himself to be, it is necessary that

he should be in a position to verify his findings by the actual experience of the confinement. This linking up of ante-natal obstetric work with the confinement is the only means whereby ante-natal care can be put on a sound and scientific basis and the true meaning of the ante-natal conditions can be properly understood and emergencies avoided.

I have confined my remarks to the ante-natal work of local authorities, but the principles on which ante-natal care, in my opinion, should be founded are not altered because the confinement is to be carried out under private auspices. Such confinements include: (1) those conducted at home by midwives; (2) those conducted at home by general medical practitioners; (3) confinements in private nursing homes or wards by general medical practitioners. In these cases either the ante-natal supervision as here envisaged is inadequate, or the obstetrician has not such experience or equipment as to enable him to cope with every obstetric condition or emergency. The fact that a consultant obstetrician is at call is not sufficient. A consultant is usually called in after an emergency has arisen. If there is a practitioner of experience in these matters at hand it seems to me essential, if the best results are to be obtained, to make use of his services from the beginning, and not wait until it is evident that special and perhaps extreme measures are required.

Ante-natal Care and the Child

I have not dealt with the effects of ante-natal care on the child. This is a subject to which I have given consideration, but in respect of which I cannot submit any satisfactory information. The fact that the mortality rate of children under 4 weeks has undergone little change since 1918, while the mortality rate of children under 1 year has been considerably reduced since that date, would seem to indicate that our present methods of ante-natal and possibly intra-natal care have not effected any material change in the healthiness of the offspring. Here it would appear to me that the obstetrician has to extend the scope of his work to include the child under 4 weeks, and to correlate his ante-natal work and the nature of the confinement with the condition of the child at birth.

How to Obtain the Best Results

Much has been achieved in respect of the establishment of ante-natal centres by the Ministry of Health, and although it is impossible to assess the value of these centres at the present time I have no doubt that their work will prove to be the most valuable of any that is done for the national health. In order that we may get the full advantage of ante-natal work, discussions like the present are of great value. Their value would be considerably enhanced if local authorities and practitioners would keep a detailed record in every case of the following among other facts:

1. The nature and the amount of ante-natal supervision.
2. The general health and state of nutrition of the patient during pregnancy.
3. The obstetric state as recorded ante-natally.
4. Noteworthy features of the ante-natal period—for example, the co-operation of the patient, the presence of some abnormality, or the need for a period of hospital treatment or the like.
5. The anticipated course of the labour.
6. The actual course of the labour.
7. Noteworthy features during the puerperium.
8. The general health of the mother and the state of the pelvic organs at some later period, say three months after confinement.
9. The condition of the child at birth as anticipated ante-natally.

AUG. 4, 1934]

SODIUM EVIPAN

10. The actual condition of the child at birth.
11. The health of the child some time after birth, say at three months.

In the foregoing I have set out the best methods of ante-natal supervision as they appear to me in the present state of knowledge. As these are not in general use, and as no standard method has been laid down or applied, it is practically impossible to assess the value of ante-natal care from the gross results which are available. If, however, the different authorities and practising physicians could be persuaded to keep records such as I have indicated, we should shortly have the necessary information to enable us to arrive at such a valuation, and to decide how best we can achieve satisfactory ante-natal supervision.

The history of medicine shows that obstetrics in the limited sense has always been regarded as a special art. The present discussion raises a wider problem than the art of obstetrics, because the nation to-day is interested in the rearing of a healthy race. The care of the mother and the child is therefore all-important. Indeed, it seems to me that this should be a division of medicine for special study and practice. A new kind of specialist is required: one whose functions would be first, ante-natal care in its wide sense, having regard to both the mother and the unborn child; secondly, the confinement of the mother; and, thirdly, the care of the mother and child for a period after the birth. A wider specialism on these lines would, I believe, secure better results in the rearing of healthy children than specialisms limited, as at present, to the much narrower fields of obstetrics and gynaecology on the one hand and paediatrics on the other.

PHARMACOLOGY AND THERAPEUTICS OF SODIUM EVIPAN

WITH SPECIAL REFERENCE TO ABNORMALITIES
UNDER EVIPAN ANAESTHESIA

BY
GERALD SLOT, M.D., M.R.C.P., D.P.H.
PHYSICIAN TO THE ROYAL WATERLOO HOSPITAL, AND ROYAL HOSPITAL,
RICHMOND; CONSULTANT PAEDIATRICIAN TO THE L.C.C.; PHYSICIAN

AND
A. H. GALLEY, M.R.C.S., L.R.C.P.
SENIOR HOUSE ANAESTHETIST, KING'S COLLEGE HOSPITAL

Sodium evipan has now definitely established itself as an anaesthetic both in medical and in dental practice, and the purpose of this article is to give a short account of its pharmacology, and the pathology of such cases as have come under the authors' notice.

Sodium evipan is the soluble salt of a new barbituric acid derivative: *n*-methyl-C-C-cyclo-hexanyl-methyl barbituric acid. It is not a volatile anaesthetic, but is rapidly detoxicated by the liver, and it is stated upon its decomposition within the narcotic dose within thirteen minutes.¹ Kennedy has also shown that detoxication of sodium evipan in mammals is very rapid.² Another characteristic of this drug is its high therapeutic quotient. In a cat this is represented by the figure 4, since 25 mg. generally gives full anaesthesia, while 100-110 mg. is the lethal dose.³ In the dog the quotient is 3.3. It may fairly be inferred, therefore, that only 20 to 30 per cent. of the lethal dose is used to produce clinical anaesthesia, and this factor must be noted when criticism of the unreversibility of evipan is made. Traces of the unchanged substance are found in the urine, but it is mostly eliminated in the form of urea.

During narcosis the blood pressure may fall by not more than 20 mm. Hg. and respirations are depressed both in rate and in amplitude.⁴ Overdose causes the cessation of respiration, the heart continuing to beat until secondary heart failure occurs, due to anoxaemia. Kennedy and Narayana have shown that the depressant action of sodium evipan on the frog's heart is very rapidly removed by washing, and is antagonized by adrenaline. The obtained complete recovery in a few seconds. The ventricle, apparently, is affected before the auricle; when the beats had completely ceased excitability still remained.⁵ Even while suffering from overdose, some animals have been kept alive by artificial respiration until enough of the drug had been excreted to allow the respiratory centre to resume normal function.

Technique of Administration

The technique of administration is well known, and consists of the intravenous injection of a 10 per cent. solution in sterile distilled water. This solution is made up immediately prior to injection, and is run in at rates which vary with different operators. An average figure would be about 1 c.cm. in ten seconds, although we, personally, deliver the first 2 c.cm. with greater rapidity. A common indication of the dose is to instruct the patient to count aloud, to note the volume given before unconsciousness supervenes, and to give the same volume again, or more, according to the duration of anaesthesia required. The symptoms produced by the injection are dramatic. While the first 2 c.cm. are entering the circulation the patient counts aloud with great confidence, but during the administration of the third c.cm. he usually begins to hesitate; a surprised look comes over his face, rapidly followed by a vacant stare, the counting becomes disordered and whispered, and finally with a deep sigh or yawn he drifts into anaesthesia. Unconsciousness usually occurs about the time of "hesitation," and is immediately preceded first by a feeling of intoxication and then by intense drowsiness. Respiratory and circulatory changes have been mentioned above, and the problem of "twitchings" will be dealt with later.

Duration of Anaesthesia

It is sometimes difficult to estimate the time during which anaesthesia occurs, since with identical doses different patients have remained anaesthetic for as little as five minutes and as long as an hour, but in most cases as five minutes and as long as an hour, but in most cases fifteen to twenty minutes can be promised with certainty. For recovery, four hours or longer is the general rule, varying according to the dose and the constitution of the patient. In neurotic people the recovery period is frequently accompanied by emotional crises, but people of stable temperament usually recover quite quietly. The patient generally remembers nothing either of anaesthetic or recovery period, except the fact that he has slept well. Abel and Jarman rightly point out that with "minimal doses" (that is, injecting 2 c.cm., waiting thirty seconds, and giving the third c.cm. cautiously until unconsciousness occurs, and then discontinuing the anaesthesia lasts from five to fifteen minutes; the patient then wakes, is quite rational, and after half an hour's rest, or sleep, is often able to walk home.⁶ It must be stressed that until recovery is complete the usual tests for sobriety are not satisfied, and the patient should be allowed to rest in quiet until feeling fit. We only know of one case of nausea or vomiting after recovery; this was in a man who was sent home on a tram, having previously had a large draught of black coffee. In a few cases headaches have been recorded (always after large doses), and these are usually likened to the aftermath of alcoholic excess.

In order to lengthen, deepen, and stabilize evipan anaesthesia some workers, Abel and Jarman,⁷ have recommended injection of an ampoule of omnopon 2/3 grain and scopolamine 1/150 grain one hour before operation. On the other hand, the Anaesthetic Committee of the Medical Research Council⁸ decided that it was inadvisable to give any sedative. In our practice we have found that the combination of sedative premedication and evipan has never given the slightest anxiety in adults of moderate health.

Difficulties under Anaesthesia

The first difficulty that occurs is at the onset of anaesthesia, when the muscles attached to the jaw become relaxed and the patency of the airway is imperilled. To prevent this, an assistant should be at hand to turn the head to one side and lift the jaw if necessary. If neither of these manœuvres is successful it is better to insert a Hewitt's airway.

Muscular twitchings are another nuisance, both to anaesthetist and to the surgeon, for they may either jerk the needle out of the vein or hinder the operative procedure. These movements are independent of stimuli, although they are accentuated and become vaguely purposive during skin incisions. Sedative premedication diminishes this trouble, however, and a further injection of a few centimetres of evipan completely abolishes the movements.⁹

We have had one case where 10 c.cm. of evipan produced amnesia but no signs of anaesthesia. The patient, however, was also in attendance at a mental hospital near by. This man took the usual four hours to recover, in a delirious manner. We have also first-hand knowledge of another case (also that of a mental patient), who showed merely drunkenness after 20 c.cm. was injected into a large vein. One of us (G. S.) has had two cases, both in men, in which the full dose of 10 c.cm. of the 1 per cent. solution was given without any kind of anaesthesia being produced nor any apparent change, either physically or mentally. Witnesses of all these inductions were fully satisfied that the injection was intravenous.

In our experience one difficulty has been that of respiratory spasm, which sometimes involves the glottis and occurs early in anaesthesia. The patient goes a blue colour, has sighing respirations, and the condition may become an alarming one; it clears up readily, however, with the passage of an intratracheal catheter. We have also had patients who stopped breathing for a time, but who, fortunately, started with artificial respiration or intubation. One or other of us has had experience with the following cases.

CASE I

A woman, aged 65, attempted suicide by cutting her throat. The larynx was exposed and opened, and evipan 3 c.cm. was injected for the purpose of induction. Unconsciousness was immediately followed by inhibition of respiration; the pulse was normal in rate and volume. Breathing recommenced on the introduction of an intratracheal catheter, and an inhalation anaesthetic was continued through it. The patient recovered consciousness about an hour after the operation ceased. The repair was successful, but the patient died five days later. Post-mortem examination revealed that bronchopneumonia was the cause of death.

CASE II

A man, aged 62, was admitted after two days' unsuccessful treatment for severe epistaxis. He had a large aortic aneurysm, and was chronically bronchitic; his weight was about 15 st. Nine c.cm. of evipan was administered for the thorough packing off of the nose. Respiration ceased; the pulse was good but the colour bad. On the introduction of an intratracheal tube respiration recommenced, and about half a pint of gastric contents containing altered blood was regurgitated. The packing was completed and the patient recovered consciousness. Two days later 10 c.cm. evipan was administered

for repacking without any untoward effect. Three days after the second operation the man died, and post-mortem examination revealed the existence of diffuse meningitis.

CASE III

In this case, that of a man aged 70, an operation for the insertion of radon into an extensive lingual carcinoma was performed. The patient was toxic, and was suffering from chronic bronchitis. Omnopon 1/3 grain and scopolamine 1/150 grain were injected an hour before operation, when 8.5 c.cm. of evipan was given intravenously. Breathing became progressively more shallow, and ceased about ten seconds after the completion of the injection. The face was cyanosed and the pulse became imperceptible. The insertion of an intratracheal catheter was followed by a sigh, and artificial respiration, which had been commenced before intubation, was discontinued. Breathing was irregular at first, but became rhythmic by the time carbon dioxide and oxygen were insufflated through the tube. Owing to the return of the cough reflex the tube was soon withdrawn, without any ill effect.

At the end of the operation the corneal reflex was brisk, and an hour later the pharyngeal reflex was also active. Six hours later the pulse became poor in volume, and the patient's colour unsatisfactory. Intravenous coramine 2 c.cm. produced a temporary improvement, which was maintained for a short while with carbogen inhalation. The pulse and respiration rates steadily rose, however, to 40 and 140 respectively (even after temporary discontinuation of carbogen) and the temperature to 101°. Breathing was bubbly, and some oedema at the lung bases was detected. Atropine 1/100 grain and digitaline 1/100 grain were injected intravenously, but the condition steadily declined. The patient died sixteen hours after operation, never having recovered consciousness. At post-mortem examination the chief pathological changes were: (a) carcinoma of the tongue; (b) fatty myocarditis; and (c) oedema and congestion of the left lung. Microscopical section showed (a) congestion of the spleen, (b) cloudy swelling of kidney and of heart muscle, and (c) a few necrotic areas in the lung.

CASE IV

A man, aged 56, of plethoric type, who had sustained several injuries through riding, was admitted complaining of sciatica. An epidural injection of novocain and manipulation was contemplated. The injection of evipan to secure anaesthesia was started in the usual way, and after 5 c.cm. the patient went an intense plum-blue colour, and after two or three sighing respirations ceased breathing. The injection was stopped immediately, the tongue was pulled forward, and some frothy mucus, which had collected in the mouth, was removed. Artificial respiration was begun, and in about half a minute the spasm of the glottis passed off and a normal evipan anaesthesia supervened. The patient was unconscious during the time of the cyanosis, and remained so for a period of about ten minutes.

CASE V

A woman of slight build, aged about 40, also suffering from sciatica, as in Case IV, was admitted to hospital for similar treatment. She also ceased breathing after about 5 c.cm. had been administered, and went a deep blue colour. An intratracheal catheter was not available, as the operation was being performed in the ward. The airway was cleared and artificial respiration started, and after a period of three or four minutes the spasm passed and she again breathed normally. Pituitrin and adrenaline were administered immediately without any obvious result. During the spasm the pulse was perceptible but very feeble. It is clear that the condition was one of glottic spasm and failure of the respiratory centre without involvement of the cardiac centre.

The following complication is recorded by Drs. Landau and Wooley¹⁰ in a patient of 23, who was admitted for a minor operation. The patient complained of headache following the operation, which became severe on the third day, when the heart rate dropped to 40 and drowsiness supervened. No other abnormality was detected. The urine was normal. The patient was treated with atropine, adrenaline, and hypertonic intravenous glucose, which

SODIUM EVIPAN

AUG. 4, 1934]

caused the attack to become less severe. The pulse gradually rose to normal, and he made an uninterrupted recovery.

In two of the preceding cases direct laryngoscopy revealed that the vocal cords were in abduction, while in Case I a Magill's tube (passed transnasally) entered the larynx with the greatest facility, and could be seen *in situ* during operation. Artificial respiration demonstrated the patency of the airway in Cases I, II, and III, as the recommencement of respiration was immediately consequent upon laryngeal intubation and occurred before the catheter could be connected to the gas-oxygen machine. Cases IV and V, although not viewed by a laryngoscope, appeared to be conditions of glottic spasm which eventually yielded after prolonged artificial respiration. The fact that the cough reflex returned so rapidly once breathing recommenced seems to suggest that a temporary inhibition of the respiratory centre occurred rather than any undue depression. Furthermore, stimulation of the vocal cords seems to have overcome this inhibition, and so enabled normal respiration to reappear in a perfectly satisfactory manner. In Case III death was partly due to respiratory failure, but several other factors contributed to this besides the previous administration of eviphan.

Fatalities under Anaesthesia

A number of cases are on record of death following eviphan anaesthesia, and for details of some of these we are indebted to Dr. G. H. Morrison.

CASE I

A man, aged 67, with extensive disease of the kidneys, myocardial degeneration, and bronchitis, was given 7 c.cm. of eviphan for the excision of a growth of the knee. He died under the anaesthetic, and the verdict at the inquest was that "Death was due to chronic heart and kidney disease, accelerated by eviphan anaesthesia."

CASE II

This was a case of a young woman, aged 27, who was in hospital for appendicectomy. She was given 10 c.cm. of eviphan, but died during the operation. The post-mortem examination showed a persistent thymus, and the verdict was "Death by misadventure."

CASE III

A man, aged 64, had chronic myocarditis, circulatory failure, oedema, and hydrothorax. Because of the toxæmia derived from his mouth, he was given 10 c.cm. of eviphan for the extraction of eight teeth. The operation was decided upon in the faint hope that the extraction might keep the patient alive for a few more weeks. He died shortly after the teeth were taken out, and the verdict at the inquest was "Death by misadventure due to syncope while under anaesthetic, to wit, sodium eviphan."

CASE IV

A woman, aged 50, received the anaesthetic prior to an operation on the jaw for removal of some septic teeth. Respiratory and heart failure, which followed the injection, was obviously due to a far advanced pathological condition of the heart. The verdict was "Death by misadventure."

CASE V

A woman, aged 60, had very severe rheumatoid arthritis. She was given 5 c.cm. of eviphan before she fell asleep, whereupon a further 1 c.cm. was given in order to extract three very septic and painful teeth. She died at the conclusion of the operation, and a post-mortem examination showed extensive myocardial degeneration and a very advanced state of rheumatoid arthritis. The coroner's verdict was "Death by misadventure due to syncope while under eviphan anaesthesia."

We are indebted to the Westminster Hospital for the report of the following case:

CASE VI

A woman, aged 42, with four years' history of bronchitis and asthma, was admitted to hospital three weeks before death with cardiac failure, which was secondary to her lung condition. Her physical signs on admission were dyspnoea, oedema of the ankles, liver enlargement, and dilated right heart. She improved considerably under treatment, and was due to be discharged on the day following her death. She had gross dental sepsis, and the physician in charge of her case decided that a clearance was necessary. Previous local injection of cocaine had prompted an alarming attack of asthma, so the anaesthetist decided to give her eviphan, as there was now no palpable enlargement of the liver.

Three c.cm. of eviphan was administered into one of the antecubital veins, the patient being in bed in the ward. She gave a typical yawn and then immediately showed signs of obstruction, with rapid and marked cyanosis. The injection was stopped, her airway cleared, and when her head was hung over the edge of the bed another breath was taken. By this time, however, she was pulseless, and in spite of carbon dioxide and oxygen, artificial respiration, intracardiac adrenaline and cardiac massage, she did not recover. Dr. John Taylor, at the post-mortem examination, found marked bronchitis, right-sided enlargement of the heart, and a nutmeg liver. A piece of tartar the size of a tooth had got lodged in the glottis, and in his opinion the inhalation of the tartar, presumably during the eviphan yawn, had caused the spasm, and the effort at inspiration had proved too much for the already diseased heart. The condition here does not seem to have been caused primarily by eviphan in view of the small dose and the direct incitation to glottic spasm by the presence of a foreign body.

Cutaneous Idiosyncrasies

Although some papers state that a cutaneous wheal in animals has caused no irritation, in one case in our experience, where eviphan was administered to a fat patient (and some must have escaped from the vein during injection), the arm became swollen and a local abscess developed not unlike that which one experiences after leakages during the use of N.A.B. We have had experience of another case of the same sort where actual suppuration did not occur, but the arm was tender and swollen for four or five days. The pain was readily relieved by antiphlogistine poultices and aspirin. These have been the only two instances in a large series, and it is interesting to note that in a batch of asthmatics, who were anaesthetized for the purpose of dental extractions, we have had no difficulty of this kind.

Dr. G. A. Grant Peterkin¹¹ reported the case of an anaesthetist who came to him with an intermittent rash on his hands and fingers. It took the form of a papulo-vesicular eruption. From the history this was thought to be a contact dermatitis, and, after several cutaneous tests, was found to be due to contact with sodium eviphan solution. The anaesthetist remembered cutting himself while making up the solution from the glass ampoules. So far as we know this is the only case of the sort that has occurred.

Miscellaneous Uses

We have used eviphan therapeutically in cases of chorea, and one of us has reported an instance in the *Lancet*.¹² The patient is usually a child, and the doses are given daily up to 5 c.cm. We have had no untoward experience with this condition; 1½ c.cm. produces drowsiness but not sleepiness in a child of 8, while 1 c.cm. usually effects temporary anaesthesia.

Eviphan was also used by one of the authors (G. S.) under the following circumstances.

A patient, about 45, who suffered from a severe head wound contracted during the war, was constantly liable to attacks of Jacksonian epilepsy. He was well known to the ambulance men of the hospital, and these attacks frequently lasted for

over an hour, and were associated with great emotional disturbance, shouting, and other evidence of cerebral irritability. On one occasion, while we were doing out-patients, this man was brought into hospital in a typical state of epilepsy; four attendants were necessary to hold him down, and he was very violent and twitching all over. He was given 10 c.cm. of evipan intravenously and his condition quieted at once into normal evipan sleep; on recovery, about an hour later, he was far less excited and almost normal.

This is the only case so far in which opportunity has occurred of using this drug in this way, but it would seem to indicate further possibilities for exploration. Doses of 5 to 10 c.cm. have also been used with success in cases of renal and gall-stone colic.

Conclusions

Sodium evipan in the majority of cases can be considered a safe anaesthetic. It should not, however, be administered single-handed, in view of the possibility of respiratory spasm, or of obstruction of the airway, which may occur while the doctor's attention is engaged elsewhere. Evipan can be repeated on several occasions without ill results; it is not advisable to follow the injection with chloroform; gas and oxygen being the ideal or, where thought necessary, ether.

Premedication with omnopon and scopolamine is a useful adjunct to anaesthesia, and, owing to the high therapeutic quotient of the evipan, and its rapid detoxication, does not carry with it the usual dangers so popularly ascribed to the clandestine association of morphine with the other barbiturates. As Moncrieff¹³ points out, however, the double depression produced by the combination of morphine and drugs of this type may cause respiratory failure, and we strongly deprecate preliminary sedation in patients who are bad anaesthetic risks. It would appear that the most valuable treatment in cases where respiratory depression has supervened would be the inhalation of a mixture containing oxygen and 7 per cent. carbon dioxide,¹³ though in a case above described this proved of no avail. Artificial respiration of itself is unlikely to be useful because carbon dioxide is washed out of the lungs; in combination with the above-mentioned inhalation, however, this difficulty is remedied. Although we have as yet had no experience with alpha-lobeline, we have not been impressed with the efficacy of stimulants. In those cases where we used coramine, it produced at most a temporary improvement, although given by the intravenous route. It is significant to note that, in the fatalities reported, the patients have been extremely ill, and most of them have died of respiratory failure.

Four practical points that seem to be evolved are as follows:

1. To avoid using the drug in cases of severe liver embarrassment, because detoxication cannot occur efficiently.

2. Where there is any question of depression of the respiratory centre—for example, in operations for cerebral tumour, or severe lung conditions—evipan would seem to be contraindicated.

3. In cases where evipan is contraindicated, but after careful weighing of risks it is thought to be the safest method of anaesthesia, it should be given alone without reinforcement by other drugs; the dosage should be cautious, and a preliminary injection of atropine should be administered with a view to counteracting the tendency to oedema of the lung.

4. Facilities should be at hand to administer oxygen and carbon dioxide mixtures ("carbogen") containing a minimal proportion of 7 per cent. CO₂ either by mask or, where necessary, via an intratracheal catheter in cases which are considered to be bad anaesthetic risks.

INJECTION TREATMENT OF COMPLETE RECTAL PROLAPSE

WITH REPORT OF TWO CASES

BY

ARTHUR S. MORLEY, F.R.C.S.

The treatment of ordinary haemorrhoids by submucous injection of carbolic acid in almond oil has become a well-recognized and ordinary procedure, and since I introduced this particular technique into England in 1928¹ it has been very extensively adopted. I notice, however, that many writers upon the subject still emphasize the importance of a very careful selection of cases, and many of them have said that cases of haemorrhoids with marked prolapse requiring digital reposition are unsuitable for any treatment short of operation, except as a palliative. I have always dissented from this view, and have treated a very large number of such cases by submucous injection with gratifying success.

I describe below some cases of *complete prolapse of the whole rectal wall* which I have treated by means of injection, and I urge that a conscientious trial of this method should be made by other rectal surgeons before submitting patients to one of the ordinary operations for rectal prolapse. All operations for rectal prolapse are severe, and all are very liable to failure. It follows, therefore, that if there is a less dangerous and less drastic method of treating patients suffering from this distressing condition it is worthy of trial, even if the relief it gives is only temporary. One of the greatest advantages of treatment by injection is that it is an *ambulatory* method—that is, it does not necessitate any confinement to bed.

Of operations for rectal prolapse one of the most generally employed is that of Lockhart-Mummery. In describing his operation² Lockhart-Mummery writes:

"*Treatment After Operation.*—The wound is dressed twice daily and fresh dressings applied, but the packing is not removed for a week. At the end of this time an anaesthetic is given and the packing removed, and a fresh lot of gauze introduced. . . . The wound should not be allowed to heal under three weeks; in fact, the more slowly it heals the better the result. The bowels are kept confined until the seventh day after operation, when they are relieved by an enema before the removal of the packing; after this they are opened daily with an enema, a slipper bed-pan being used. The patient is not allowed out of bed for six weeks, and not allowed to sit up for an action of the bowels for two months at least. It is most important, in view of the large area of cellular tissue opened up, that there should be no sepsis at the time of the operation, but sepsis later is almost certain to occur after the removal of the packing, and is of no consequence" [sic]. "The slower the wound heals, and the more fibrous tissue involved, the better the result. Out of a total of thirty-two cases there have been only five failures" [that is, a recurrence rate of over 15 per cent.], "and two of these were permanently cured by repeating the operation."

INJECTION TREATMENT OF RECTAL COLLAPSE

AUG. 4, 1934]

Most people will not look forward with pleasure to such a programme as this, and, if one can tell a patient honestly that there is any hope of avoiding such a prospect by means of injection, I doubt whether one is to be found who would not cheerfully accept the risk of recurrence in order to do so—more especially if he is told that there is at least some risk of recurrence even after the most skilfully performed operation.

Of the other methods of operation for prolapse—by means of linear cauterization of the rectal wall, Whitehead's operation, sigmoidopexy and excision of a portion of the bowel with end-to-end anastomosis—all have the same grave objections from the patient's point of view. All involve long confinement to bed, all have a very definite mortality rate, and all have quite a high percentage rate of recurrence and failure. In elderly patients most surgeons would hesitate to recommend such operations, because for them the risk is very real.

Case Records

Case 1.—In October, 1929, I saw a lady, aged 58, who had suffered from rectal trouble for eighteen years. It had commenced with the ordinary symptoms of haemorrhoids—bleeding after defaecation, followed shortly by prolapse, at first after defaecation only and then by prolapse on walking, exertion of any sort, and even on sneezing. Gradually a condition of complete incontinence of faeces had developed. When I saw her she was in a wretched condition; her clothes were always stained with faeces, mucus, and blood, there was considerable emaciation, and she was extremely depressed. Perhaps fortunately for her, there was considerable constipation. On examination, the sphincter was quite lax, and it hardly contracted when she was asked to grip the examining finger. The anus looked almost as if a Whitehead's operation had been performed upon it. On straining, about 3½ in. of the whole bowel wall prolapsed completely. The speculum, when introduced, practically "dropped in." She had some extremely large internal haemorrhoids, extending for some two inches up the rectum. The mucous membrane was ulcerated and inflamed from friction against her clothing.

She absolutely declined to submit to operation, so with considerable hesitation I consented to see what I could do for her by means of injection. When she came for her second injection at the end of a week she reported that though there was still slight prolapse, there was marked improvement, that she had much more control over defaecation, and that she had had no inconvenience from the treatment, excepting slight pain for four hours after it. After the second injection she reported that there was no further prolapse at all, in spite of some exercise, but she still had some loss of control if the motions were liquid. She had five injections at weekly intervals, and after that she reported that she felt better than she had done for years, and there had been no prolapse from after the second injection, although there was still slight incontinence for liquid motions. Her constipation was being regulated by means of Kaylene-Oil, and she had been told to endeavour to adjust the dose so as to keep the motions formed. In this way she was able to control about in comfort, but she was not able always to control flatus. I found that all the piles were quite hard and small, the rectal wall was holding up perfectly, but the sphincter was still very lax.

She returned in September, 1930—eleven months later—reporting that up to the previous May and June she had been perfectly comfortable. Since then there had been a return of the lack of control of flatus, and, to a less extent, of liquid faeces, and more recently there had been slight prolapse on defaecation. Her weight was steady and satisfactory. I found no definite haemorrhoids, but the rectal mucosa was again lax and voluminous. She had four more injections, after which she said that she was "extraordinarily better," and that there was no prolapse or leakage even during an attack of diarrhoea. She came again in May, 1931, complaining of slight return of incontinence of flatus and liquid faeces, and I found that there was still no trace of piles, but that the anterior rectal wall prolapsed slightly on straining, and the sphincter remained very lax. She had one injection then and another on her next visit to London a

month later. I urged her to undergo a plastic operation to repair the sphincter and to narrow the anus, but she would not consent to do so.

Her next appearance was exactly a year later, when she said that she had remained well again for six months and that after that the prolapse had reappeared and had been gradually increasing; she had been a little incontinent again for the past two months. I again found a complete absence of haemorrhoids, but the mucous membrane was again loose and voluminous. I gave her three further injections. After that she remained well until March, 1933, again reporting a slight relapse after six months of complete comfort. She had three further injections. I had a satisfactory report from her in June of that year.

I fear that she is likely to have further relapses, but she is prepared to face these and to have further injections, rather than even to undergo a somewhat unimportant plastic operation to narrow the anus. Throughout the whole series of injections the only trouble and complications that she experienced were occasional pain for four to six hours after injection, and on two or three occasions some pyrexia for twenty-four hours after treatment.

Case 2.—An unmarried woman, aged 75, had had rectal trouble for seven or eight years—gradual loss of control over the bowel, considerable mucous discharge, very occasional bleeding and prolapse, the onset of which coincided with the appearance of the incontinence. She had been previously diagnosed as "colitis and prolapse," and advised that she was too old for any radical operation. Colonic irrigation produced some temporary benefit, but never real relief, either to the prolapse or to the incontinence.

On April 20th, 1933, I found the sphincter extremely lax, but fairly active. There were some moderate-sized internal haemorrhoids, and a huge prolapse of the whole bowel wall when she strained. I injected this all round as high up as the lower six inches. I injected her haemorrhoids. At her next visit she reported that she was "greatly relieved." There was no prolapse after walking, but still a little after it extended, and also injected her haemorrhoids. At her next visit she reported that she was "greatly relieved." There was no prolapse after walking, but still a little after defaecation; the mucous discharge had ceased, and the incontinence was less. After her third treatment the prolapse had entirely ceased, even after defaecation, but there was still slight lack of control. At her fifth visit she reported herself quite comfortable, and stated she had spent three hours at a flower show without discomfort or fatigue. After that she went to stay in Scotland for three weeks, but I saw her again in June and gave her two more injections. She had no return of the prolapse, her bowels were acting less erratically, and she had less incontinence. I saw her twice again in August, and there was no return of the prolapse, but still incontinence of liquid faeces. On November 8th the patient wrote to me from South Africa that she was keeping perfectly well. She added: "The control is very much better. I have recovered from a pretty severe cold and cough, but now coughing does not trouble me at all."

It is too soon after six months to claim this case as a "cure"—indeed, I rather anticipate that there will be a recurrence sooner or later. However, if there is any tendency to relapse, she will have a few more injections, and, I hope, another year's relief.

Discussion

In both of these cases there was quite definite prolapse, not merely of internal haemorrhoids, but of a considerable length of the whole rectum. Both had toneless sphincters with obliteration of the anal canal, and both of them complained chiefly of incontinence of faeces. I do not suppose that complete relief will be permanent in either case—indeed, the first of these patients has been coming annually since 1929.

The technique differs slightly from the method of injection of internal haemorrhoids with phenol in almond oil which I described in 1928, in that for the high injection in true rectal prolapse one aims at inserting the needle slightly deeper than the submucous tissue. It should be introduced deeply enough to reach the muscular coat. If this is done successfully the swelling produced by the oil in the submucous tissue does not appear to the same

extent, and the "striation sign" that enough has been injected at any particular spot does not occur. One is reduced to guess at the correct amount. I have usually injected 2 to 3 c.cm. at each puncture. The aim is to inject all round the rectal wall. After two or three treatments, if one feels the rectum from the vagina, the whole bowel feels hard, and the sensation closely resembles that produced by an annular carcinoma of the rectum when felt from the vagina. All this thickening disappears some three or four weeks after the completion of the treatment. This inflammatory process results in close adhesion of the mucous and submucous coats to each other and to the muscular coat. This in itself prevents the bowel wall from prolapsing, and, moreover, the submucous space being more or less obliterated, the main haemorrhoidal vessels which feed the piles are compressed and the haemorrhoids are cured in that way.

This method of treating true prolapse, like the submucous injection of haemorrhoids, was first carried out in the United States. Considering how unsatisfactory the treatment of this condition by operation has proved, I hope that others will give their patients the option at least of trying injections before resorting to more drastic operations, with their discomforts, dangers, and uncertainties.

ADDISON'S DISEASE DUE TO MALIGNANT INVOLVEMENT OF THE SOLAR PLEXUS

BY

FRANKLIN BICKNELL, B.M., B.Ch. OXON
MEDICAL REGISTRAR, ST. THOMAS'S HOSPITAL

It is generally stated in textbooks that one of the rarer causes of Addison's disease is the involvement of the solar plexus and semilunar ganglia by malignant growth. Rolleston¹ says:

"There are cases in which symptoms like those met with in Addison's disease are found in association with alteration of the semilunar ganglia or abdominal sympathetic, the suprarenals appearing healthy. Thus the solar plexus and semilunar ganglia have been surrounded by lymphadenomatous growth, whilst the suprarenals were found to be intact."

However, very few such cases have been recorded in the literature. Addison's tenth case was probably of this nature, but after the collection made by Lewin,² who found healthy suprarenal glands in 12 per cent. of cases reported in the literature up to 1892, I have not been able to find such a case. Rowntree and Snell,³ after reviewing the work of the Italian clinicians Pende and Varvaro,⁴ state: "One may infer that there is a possibility of functional suprarenal insufficiency depending on interference with secretory nerves to the gland; however, we have not observed such a case in our series." Neither was any such case reported by Conybeare and Millis.⁵

The following case, besides the fact that the symptoms were presumably due to involvement of the solar plexus, and not the capsule, by malignant growth, is also of interest as regards the darkening of the hair and the high blood sugar.

Sir W. Wilkes⁶ stated that only one or two cases were recorded where the hair had darkened in Addison's disease, and though it is stated⁷ that "the hair often becomes darker," this is not a symptom which I have found recorded in any individual case. The fasting blood sugar is usually low or well within normal limits⁸; not, as in our case, as high as 0.137 per cent.

Case Record

The patient, a man of 50, was first seen at the end of August, 1933. His family history was entirely uninteresting, and his own past history was uneventful. He only remembered having measles, and becoming very freckled as a child in the summer. During the war he served in France, and since then had been a caretaker.

History.—Some time in 1930 he began to get epigastric pain after his meals: this pain was relieved by alkalis, and did not seriously worry him, although it never completely disappeared. In April, 1933, he noticed that he was more sunburnt than usual, and at the same time his abdominal pains became more severe and different in character. He got steadily worse until the end of August. His face, hands, and forearms grew progressively darker in colour; his body as a whole did not become pigmented, save to a slight degree over his abdomen. The whites of his eyes and carunculae he noticed remained normal. His nipples and genitalia became a deep black. His hair and moustache, which had been turning grey, became much darker, "as if he were becoming younger." There also appeared small discrete dark spots over his trunk and arms. Periodically the pigment grew much more intense, and then lighter again, so that "his face was copper-coloured, or like a negro." These sudden increases in pigmentation were always associated with severe abdominal pains, lasting about half an hour, relieved by bringing up wind, and not related to food or exercise. He also became progressively weaker, so that by August he had to stay in bed. He quite lost his sense of taste and smell—chicken, fish, and bread all tasting the same—while everything appeared to have an earthy smell.

Progress.—In September he began to feel much better. He was becoming almost normal in colour, his abdominal pains were less, and he felt he could work. An x-ray, taken at this time, showed a small lesser-curve ulcer. He returned to work for a week, but had to stop, as he began to have severe pains and vomiting. The pain became much less, but the vomiting continued, generally preceded by nausea, but leaving him feeling quite well afterwards. It had no relation to his meals. Late in November he was admitted to hospital.

Examination.—He was well covered, in spite of having lost 2 st. in the last six months. His skin was of a uniform dark yellow-brown, with darker discrete spots. The palms of the hands were pale, with the creases dark brown. The nails were normal. Pigment began sharply at the wrist. His hair was a mixture of black and grey. His moustache and axillary hair were dark brown. He stated that originally his moustache had been grey. There was a dark line on the buccal mucosa opposite the crowns of the teeth. Pigmentation was most intense over the arms, face, and genitalia. A biopsy on a piece of his pigmented skin showed no free iron. His cardiovascular system was normal. His blood pressure was 144/98 mm. Hg on admission, falling to 96/57 mm. two weeks before his death. His blood count was 3,760,000 red cells, with a colour index of 0.5; 13,000 white cells, 87 per cent. polymorphs, 10 per cent. lymphocytes, 3 per cent. large hyalines. In the epigastrium a mass of indefinite outlines could be palpated: it was thought to be a gastric carcinoma. His gastric juice contained blood, and no free HCl until after an injection of histamine, when 0.168 per cent. of free HCl was present. The faeces contained large quantities of occult blood. The x-ray of his stomach suggested a neoplasm. An x-ray of the suprarenal areas was negative. Clinically and by x rays his chest was normal; his nervous system and urine were normal; the blood urea was 42 mg. per 100 c.cm., and the Wassermann reaction was negative. Fasting blood sugar was 0.137 per cent. While in hospital the patient's condition steadily deteriorated.

Asthenia was pronounced from the date of admission, and became so marked that he could scarcely move or speak. Vomiting was incessant. He died on December 30th, 1933.

Post-mortem Findings.—I am indebted to Dr. J. L. Edwards for the following report on the necropsy. The patient showed emaciation and extreme pigmentation of a brownish type, mainly of exposed parts. The adrenals appeared normal. There was no evidence of malignancy, tuberculosis, or atrophy, but a large mass of carcinomatous glands pressed directly on to the coeliac plexus. The brain appeared normal.

CLINICAL MEMORANDA

AUG. 4, 1934]

The lungs showed confluent bronchopneumonia, with recent pleurisy on each side. The stomach showed a large ulcer, about 2 in. in diameter, immediately on the stomach side of the pylorus, which was clearly malignant, with large masses of secondary glands and many secondaries over the whole abdomen. The liver and spleen showed no secondary deposits. The kidneys appeared normal for the age. The heart showed slight ventricular hypertrophy. The parotid on the left side showed suppurative parotitis.

I wish to express my thanks to Sir Maurice Cassidy for permission to report this case.

Clinical Memoranda

VARICELLA COMPLICATED BY TETANISM

During recent years attention has been drawn by P. Bérède,¹ J. Hallé,² F. M. Fry,³ P. Mühlkamp,⁴ Laignel-Lavastine,⁵ and other investigators to the occasional incidence of nervous symptoms as complications of chicken-pox. As a rule, however, the disease runs so mild a course that even practitioners with experience of numerous epidemics have never encountered manifestations of this character. For that reason alone I feel that the following case is worthy of description.

The patient, a boy aged 4½, was brought to my surgery on April 14th, 1934. Chicken-pox was then epidemic in this area, and, after inspecting the typical eruption which the child exhibited, my colleague had no difficulty in reaching a diagnosis. On the following evening I was sent for urgently, because the patient lying with his back arched to my surprise I found him lying with his anxious over a pillow, which was being supported by his parents. The muscles of the neck, spine, and limbs were in a state of tonic spasm, and the whole posture was truly opisthotonic as that encountered in tetanus or strychnine poisoning.

When lifted he remained as rigid as a board, and when set upon his heels he was able to stand with the spine hyperextended. Without encouragement he even walked a few steps in a shuffling spastic fashion. During temporary relaxation of the spasm I found that his knee-jerks were equally increased, and that there was a bilateral knee- and ankle-clonus. In addition, he exhibited marked trismus, and the angles of his mouth were drawn down. There was no elevation of the eyebrows, however, to complete the picture of a risus sardonicus.

The child was perfectly rational, he was not unduly alarmed by his condition, and no aggravation of symptoms followed my examination.

On the third day of the illness lumbar puncture was performed, and although a manometer was not used, increased tension was obvious from the spouting of the cerebro-spinal fluid. The specimen was examined under the auspices of the Welsh National Memorial Association; it was sterile, and no abnormalities were detected. On the seventh day of the illness, as little or no improvement had occurred, lumbar puncture was repeated, and the fluid was still found to be under pressure. Twenty thousand units of antitetanic serum were administered intrathecally. Again laboratory investigation gave no hint as to any causative factor. On the ninth day of illness fluid was once more withdrawn and a further injection of antitetanic serum made.

On the eleventh day the pressure of the cerebro-spinal fluid was distinctly lessened, and in view of the following report which had been obtained no serum was administered: "Clear colourless fluid, in which nine cells per cubic millimetre were counted. Seven of these were lymphocytes and the remainder monocytes. On centrifuging the fluid yields

a very small, granular sediment, films from which show a few lymphocytes and occasional monocytes. By Ziehl no acid-alcohol-fast bacilli were seen. Globulin and sugar content were normal. The slight increase of cells may possibly be due to meningeal irritation as the result of serum therapy."

On the tenth day of illness smoky urine was voided, and haematuria gradually increased entirely by the fourteenth day. Muscular spasm commenced to diminish on the twelfth day, and from then onwards recovery was rapid. Throughout the illness there was a complete absence of oculomotor disturbances and of changes in the fundi. The child did not vomit or suffer from constipation. At the present time he is in normal health and, mentally, as alert as before his illness.

This case is no exception to what appears to be the general rule in such complications of varicella—that in spite of the alarming initial features complete recovery almost invariably occurs. It differs from the bulk of those already described in that the symptoms were essentially tetanic rather than meningitic or encephalitic.

CONCURRENT EXTRAUTERINE AND INTRA-UTERINE GESTATION

The following case is considered worthy of record because of its rarity.

A woman, aged 30, was admitted under my care to the General Hospital, Barbados, on April 15th, 1934. She complained of great swelling of the lower extremities and said that she was nearly five months pregnant. She had had one child eight years ago, otherwise her history was negative. On examination she was found to be rather pale, and greatly swollen from the pelvic girdle downward. Blood pressure, 145 systolic, 95 diastolic; temperature, 99.6° F.; pulse, 100; respirations, 20. The heart was normal. The urine was clear, and contained a mere trace of albumin.

The abdomen was about the size of a seven months pregnancy, hard and lobulated. Examination per vaginam showed a smooth, painless tumour filling the pouch of Douglas and extending down to within two inches of the vulva. The cervix could not be felt either per vaginam or per rectum. Bimanually two tumours could be felt in the abdomen, one in the midline up to the umbilicus and the other in the left upper quadrant of the abdomen.

At laparotomy, on April 18th, the bladder bulged into the wound as high up as an inch below the umbilicus, and was adherent to the anterior abdominal wall. A catheter was passed with some difficulty, and 60 oz. of foul-smelling ammoniacal urine was drawn off from two large loculi in the bladder.

The uterus was found lying below the spleen, freely mobile, about eighteen weeks pregnant, and perched upon a large pelvic hæmatocoele, which filled the pelvis and contained a foetus of about eighteen weeks' gestation, complete with umbilical cord and placenta. This foetus had been aborted through the fimbriated end of the right tube. The hæmatocoele and foetus, etc., were removed, together with the right tube and ovary, and the abdomen closed. The patient is making an uninterrupted recovery.

The points of interest appear to be: (1) Failure of repeated catheterization with a metal catheter to empty a bladder which was chronically distended and loculated. (2) The practically normal character of the urine passed naturally or obtained by a catheter before operation. (3) The extreme degree of swelling of the lower extremities due to pressure on the pelvic veins. (4) The rare association of intrauterine and extrauterine pregnancies of approximately the same period of gestation.

H. GREY MASSIAH, M.A. M.D., C.M.
Surgeon, General Hospital, Barbados.

Reviews

TREATMENT OF SYPHILIS

The Modern Treatment of Syphilis,¹ by Dr. J. EARLE MOORE, gives a very full account of the methods and drugs in current use; the text is supplemented by a number of tables, in many of which brief statistics are clearly set out showing the reader at a glance what the author intends to convey; a particularly valuable one is Table VIII (p. 29), where the author gives the prognosis of adequately treated syphilis in all its various stages. The question of immunity is discussed very ably, though the author admits that its mechanism is not understood thoroughly; and great stress is laid on the necessity of continuous treatment in early syphilis up to the point of complete sterilization.

The four types of anti-syphilitic drugs—arsphenamines, bismuth, mercury, and iodides—are reviewed, and an admirable account is given of the reactions which may be caused by the first-named; jaundice is said to represent probably "an acute infectious disease in a patient whose liver function is subject to the added strains of syphilis and of metabolizing arsphenamine." In early syphilis a strong preference is shown for the original "606" over the "neo" group: in late syphilis this is not stressed; sulpharsphenamine has been discarded except for young patients and those with difficult veins, on account of its tendency to cause dermatitis. Of the bismuth preparations the insoluble are recommended, and more particularly the salicylate. The intramuscular injection of mercury is deprecated: where this drug is used the inunction method should be employed.

Dr. Earle Moore regards the treatment of early and late syphilis as two very different problems. In the former, one may treat the disease—in the latter, one must treat the patient. With adequate treatment 90 to 100 per cent. of cures may be obtained in the former; in the latter it is rather a question of checking the progress of the disease. There is a full discussion of the relative merits of "continuous" and "intermittent" treatment; the author holds strongly to the former, and in general treats his patients with alternating series of injections of arsphenamine and heavy metal; in the case of early syphilis, however, he has been driven to modify this owing to the high incidence of neuro-recurrence, and uses arsphenamine and heavy metal concurrently at first. The real point at issue is—which is the more continuous form of treatment, alternating courses of arsphenamine and bismuth with no rest periods, or a series of arsphenamine and bismuth injections given concurrently with rest periods? On reflection it is clear that the latter is the more continuous if the rest periods are not prolonged, because all or nearly all the arsphenamine is eliminated some days before the next dose is given (when the interval is, say, a week), whilst the excretion of an insoluble bismuth salt extends over a very long period.

It is in the management of late syphilis—including latent, benign, neuro-, cardiovascular, visceral, and ocular syphilis—that the author is at his best. The purpose of treatment is first symptomatic relief and secondly consolidation of the gain to maintain the patient in good health. In such cases the type and amount of treatment must depend on a number of factors—the part or organ involved, the age and condition of the patient, and the presence or absence of complicating diseases such as tuberculosis. For neurosyphilis the three methods of choice are tryparsamide, fever therapy,

and subdural treatment. The author considers that malaria is far and away the most efficient fever-producing remedy (especially in paresis) and that other methods should only be adopted when there is some definite contraindication to it; he deprecates the fashion of exhibiting over-enthusiasm for each new method, such as diathermy, till it has been proved superior to malaria. He is a great advocate of subdural treatment in certain types of neurosyphilis—notably primary optic atrophy and intractable lancinating pains—using arsphenamized serum prepared somewhat according to the technique of Swift and Ellis.

A chapter on the interpretation of serologic tests is included. If others would take as sensible a view as the author less would be heard about the fallibility of reactions and discordance of results, and criticism of the Wassermann reaction and flocculation tests would be more intelligent. In general the teaching is thoroughly sound, but many syphilologists, in this country at any rate, will strongly disagree with the so-called continuous treatment, preferring the concurrent use of arsphenamine and heavy metal; whether the advantages of using the original "606" outweigh its disadvantages is a moot point. The book is a mine of information and is well produced, but there are far too many grammatical errors. There is a representative bibliography.

A KEY TO MODERN RESEARCH

Up to within comparatively recent times the progress of physical science related in the main to matters with which everyone was familiar, such as energy, heat, and movement. To-day the general reader has few points of contact with the entities with which physical science deals, and if he is to assimilate the results of modern research at all it is necessary that he should obtain some insight into these entities themselves, without much assistance from common knowledge. Such works, therefore, as Mr. J. G. CROWTHER's *Progress of Science*,² in which the reader is directly introduced to these entities in language divested as far as possible of technical terms, are now almost indispensable to those aiming at even a moderate degree of general culture.

Mr. Crowther gives a topical interest to some of his subjects by connecting them with the various institutions at which they are studied, such as the Cavendish Laboratory at Cambridge, the Institute of Theoretical Physics at Copenhagen, the Physico-Technical Institutes at Kharkov and Leningrad, adding to his descriptions details concerning the scientists who work at those institutions. The author describes many of the most important recent discoveries in physics, astronomy, chemistry, and biology, together with the steps that have led up to them. In the physical section are included the discovery of the neutron (the neutral elementary particle consisting of proton and electron in close contact), the discovery of the means of disintegrating atoms by artificial methods without the employment of radioactive substances, and the discovery of cosmic rays and the positron or positive electron. In the astronomical section are discussed the theories of the expansion of the universe and stellar evolution; in the chemical section, heavy hydrogen, its properties and importance.

Of more direct interest to the pathologist are the chapters describing mitogenetic radiations, Spemann's studies on the organizing power of embryonic tissue, and the chapter on heredity. The Russian scientist Gurvitch discovered that vegetable cells undergoing mitosis emit rays resembling those of ultra-violet light; these possess

REVIEWS

AUG. 4, 1934]

the remarkable power of stimulating the rate of division of the cells in neighbouring vegetable structures, and hence have been called "mitogenetic." What significance they may have in biological processes has yet to be ascertained, but it has been suggested that they may possibly have the important property of causing gene-mutation. The chapter on human heredity deserves careful study from those who advocate selection and sterilization as a means of eradicating hereditary disease. According to the author, policies for the social control or sterilization of persons of moderate degrees of mental defect cannot at present be founded on solid scientific knowledge; and while there is good evidence for the desirability of the compulsory sterilization of some few persons suffering from certain extreme and very definite disorders, there is no good scientific evidence for the sterilization of large social groups. A chapter on pernicious anaemia is added as affording a good example of the value of animal experimentation in the advancement of medical science.

URINARY INFECTIONS

Mr. CLIFFORD MORSON had a difficult task in compressing a description of urinary infections into the space of a pocket monograph.³ He has succeeded in getting round the whole subject, though this involved a considerable loss of detail. He has wisely avoided alternative methods of treatment, and has thus been able to give more space for symptomatology.

After describing the method of taking and examining a specimen of urine, the author enumerates the more common organisms found, and then discusses the paths by which infections spread within the urinary tract. The following chapters are devoted to acute colon bacilluria, chronic colon bacilluria, urinary tuberculosis, genital tuberculosis, coccal infections, infection and renal function, stone, urinary infections in childhood, and prevention and treatment of post-operative infection. It is almost impossible to discuss these varied topics adequately in a book of 76 pages, and the author has rather handicapped himself by attempting to cover so large a subject within so small a compass.

FRENCH PAEDIATRICS

With volumes iv and v, now published,⁴ the new French treatise on diseases of children, edited by Professor P. NOBÉCOURT and Dr. L. BABONNEIX, is complete, and the high standard set by the earlier sections has been well maintained. The fourth number of the series begins with the concluding sections on disorders of the digestive apparatus, and apart from this is mostly occupied by sections on the genito-urinary system, on affections of bone, of the skin, eyes, and one on psychiatry. There is also an interesting section on poisoning, including a surprising ten pages concerned with alcoholism in childhood! The various disorders of bones are particularly well described, and are the best feature of this volume. The concluding book deals with neurology and with therapeutics. Dr. Pichon describes "pink disease" under the usual French name of "infantile acro-dynia" and puts forward a claim that the disorder was first described by Selter of Solingen in 1903. The section on treatment is very comprehensive, and includes, besides a description of drugs (where national differences decrease the utility), biological methods, physiotherapy, climotherapy, and spa treatment. An index of over forty

pages, in double columns, concludes the whole work, and is very much better than we commonly find in French publications. Now that the whole five volumes are available it is possible to confirm what was said about the first—namely, that this is a worthy achievement by the French school of paediatrics, clear in expression, beautifully produced, and full of clinical wisdom.

Dr. ADDISON'S DIARY

In the *Journal* of February 24th last (p. 333) we reviewed the first volume of the Right Hon. Christopher Addison's personal diary, published under the title of *Four and a Half Years*. In the second volume⁵ now published some of the less satisfactory features recur. It was not, of course, to be expected that there would be any change in the general format of the book to make it more attractive, but the inattention to the correctness of proper names still persists. The inaccuracies which we noted are all perpetuated in the index to the diary at the end of the second volume, and in addition it is a little disconcerting to find Sir William Glyn-Jones described as Sir Glyn Jones, and to have to seek for references to Sir James Smith Whitaker under the name of Sir Thomas Whitaker Smith. A curiosity, too, is the repeated reference to the "Con-Joint Committee" of the Royal Colleges of Physicians and Surgeons.

This volume carries Dr. Addison's record from January, 1917, when he had just become Minister of Munitions, to January, 1919, when, after having been Minister for Reconstruction, he became President of the Local Government Board with a view to his early appointment as the first Minister of Health. It thus covers the last two years of the war, and the period of preparation, such as it was, to deal with matters immediately upon its conclusion. Although the author, apart from his praise-worthy and indispensable work as an excellent Minister of Munitions, had but little direct responsibility for the conduct of the war, he was closely associated with the Prime Minister and others who had this direct responsibility, and, as Minister for Reconstruction, he had a predominant part to play in many of the problems which would, after the cessation of active hostilities, become of the most urgent importance. Here, one would have supposed, was material which could not fail to be of intense interest, yet we fancy that most readers will find the diary too long, unnecessarily detailed, and not very illuminating. This volume is free from the trivialities which marred the first, but it is of uniform solemnity, sometimes rising into patches of relative interest and now and then falling into definite dullness. It is relieved by no light touches until, at page 567, we are given, at second hand, the delightful extracts from letters received by Pensions Committees from the wives of soldiers. Two of them we may quote: "Sir, I am sorry not to have answered your letter sooner, but I have been in bed with the Doctor for three months now and want a change"; and, "Sir, Please send my money quick or I shall have to lead an immortal life."

The passages which will be of most interest to readers of this *Journal* will probably be those relating to the project to establish the Ministry of Health. They will enable readers to realize the remarkable difficulties which this project encountered, and the gratitude and praise which are due both from the medical profession and from the public to Dr. Addison for his wisely directed and persistent efforts to this end, which happily was at length achieved. Some knowledge there has been of the obstinate opposition and obstruction of the old Local Government

³ *Urinary Infections*. By Clifford Morson, O.B.E., F.R.C.S. London: John Bale, Sons and Danielsson, Ltd. 1933. (Pp. 76, 2s. 6d. net.)
⁴ *Traité de Médecine des Enfants*. Tomes iv and v. Edited by P. Nobécourt and L. Babonneix. Paris: Masson et Cie. 1934. (Broche, 150 fr., relié, 170 fr., each volume.)

⁵ *Four and a Half Years. A Personal Diary from June, 1914, to January, 1919*. By the Right Hon. Christopher Addison, P.C., M.D., F.R.C.S. Vol. ii. London: Hutchinson and Co., Ltd. 1934. (Pp. 305-629; 32 illustrations. 18s.)

Board, especially of Mr. Walter Long and Mr. Hayes Fisher, as also of the ill-directed activities (at least in the earlier stages) of approved societies, but Dr. Addison emphasizes the troubles so caused. The author makes acknowledgement of the helpful services of the British Medical Association and of Lord Dawson in this matter, but he scarcely does justice to the initiative which the Association and the profession had taken in this direction long before, or to the persistent pressure which they exercised over a number of years and throughout a difficult period. He remarks that: "It is a great comfort that Morant is heart and soul for this enterprise"; and it is pleasant to find him saying, in contrast to some references in his first volume: "In the afternoon there was a deputation from the British Medical Association. It seemed like old times. I found them thoroughly sympathetic." A further entry, which it may be useful to quote, is the following: "I had dinner with some doctors, and we discussed the question of medical men being candidates for Parliament. . . . We badly need more medical men of good standing who are helpful, level-headed citizens first and experts afterwards, and who will not pose in the House or lecture it."

The whole diary, in spite of some heaviness and of some unattractive features, gives us a record of strenuous work, conscientiously and honestly performed, and of wise influence exerted in several spheres of political activity, not untouched by signs of personal antagonisms and disparagements, which to some readers will seem unnecessarily emphasized or even unjust, but with a commendable absence of intrigue and self-seeking to which there must, at times, have been no small temptation.

Notes on Books

In the foreword to his work on *Human Sex Anatomy** Dr. R. L. DICKINSON remarks that gynaecology has been too much busied with operative work to give proper time to certain fundamentals, which include normal functions, life adjustments, and certain sex problems. It is with the object of filling up these gaps that the present work, which is issued under the auspices of the United States Committee on Maternal Health, has been undertaken. The book is divided into two main parts, the text and commentary being separated from a series of 175 figures, which form a topographical atlas, by a copious bibliography of Anglo-Saxon and foreign literature. The following subjects receive detailed consideration: (1) conditions favourable or unfavourable, for conception; (2) conditions favouring or handicapping ideal sexual intercourse; (3) physical conditions productive of painful intercourse and frigidity in women; (4) conditions bearing on coitus during pregnancy; (5) anatomical conditions affecting (a) contraceptive devices, (b) abortion, (c) operative sterilization; and (6) anatomical findings in autosexuality. The text consists of nine chapters, dealing with the bony pelvis, the female organs of generation, male genital anatomy, the anatomy of coitus, and the anatomy of control of conception.

In an article "Physicochemical Aspects of the Photochemical Transformation of Estosterol to Vitamin D" Professor NICOLA of Buenos Aires gives an account of a series of researches, the result of which has been, in general, to confirm and amplify the results obtained by previous workers.⁷ The author has made quantitative studies of the effects of ultra-violet irradiation on ergosterol, and has determined the influence of wave-length, nature of solvent, and other variables. He also discusses the physical properties of the products, other than vitamin D, that derive from the irradiation of ergosterol.

* *Human Sex Anatomy*. By Robert Latou Dickinson, M.D. F.A.C.S. London: Baillière, Tindall and Cox. 1934. (Pp. 145; 191 figures, 45s.)

⁷ "Consideraciones fisicoquímicas sobre la transformación fotoquímica del Ergosterol en Vitamina D." By Dr. A. F. F. Nicola. Publicado en la *Revista Médica Latino-Americana*, Año xix, Enero y Febrero de 1934, Nos. 220 y 221. Buenos Aires: Imprenta Mercatali, Avenida Acayte 271.

In his book on the Dualism of the Heart Beat* the late Professor HENRIJEAN of Liège went deeply into the question of the physiological properties of the cardiac muscle, allied as it is to normal muscular tissue by its power of contracting and to nervous tissue by its ability to conduct the impulse to contract. It is not possible to summarize the many arguments and experimental observations with which the authors' theses are supported: the book is one for physiologists, biologists, and specialists in cardiac disease, and to them it may safely be recommended.

Preparations and Appliances

A RAILWAY STRETCHER

A Great Western Railway carriage cleaner at Taunton has designed a stretcher which will provide a "bed-to-bed" service for invalids or stretcher cases passing from town to town or home to hospital throughout the company's system. The standard stretcher in general use in hospitals, etc., is too wide to pass through railway carriage doors, so that in the past invalids have had to be lifted into and from the compartment, or conveyed in the guard's van. The new stretcher overcomes this difficulty. It is slightly narrower than the standard stretcher, and can be lifted straight in or out of the compartment from or to the platform or ambulance without the patient being disturbed, and, by fitting along one seat, it leaves the other side of the compartment free for those accompanying the patient.

The stretcher is fitted with a removable "shock absorber" bed, has an attachment for holding an adjustable bed-rest, and handles that slide in flush with the ends when it is not being used as an ordinary stretcher, so reducing its length to a minimum. It can also be quickly fixed to or removed from any standard stretcher fitted in ambulances or those used in hospitals, and a cross rail at each end serves as an extra means of carrying short distances and in confined spaces, or negotiating passage corners.

The "Parrott" stretcher, as it is named (after the designer), has been patented on his behalf by the G.W.R., which, during the last twelve months, has subjected it to exhaustive tests. So satisfactory have been the results and so marked the comfort afforded, especially in cases of paralysis, broken limbs, or severe surgical operations, where the invalid must remain flat, that the company proposes to provide these stretchers at Paddington, Bristol, Exeter, Plymouth, Gloucester, Cardiff, Swansea, Birmingham, Chester, and other key points throughout the system, from which they may be obtained by any station for any journey.

PROSTIGMIN

Prostigmin is a synthetic drug (Hoffmann-La Roche) which has a pharmacological action similar to physostigmine, but superior to the latter in certain respects. The chemical title of prostigmin is dimethyl-carbamate ester of 3-hydroxy-phenyl-trimethylammonium-methyl sulphate. Pharmacological investigations showed that it has a powerful action in stimulating intestinal peristalsis, but has a feeble action on the heart and circulation, and also a feeble miotic action. These properties suggested the use of the drug for the prevention and treatment of post-operative distension. Clinical investigations, arranged by the Therapeutic Trials Committee of the Medical Research Council, have shown that prostigmin, combined with pituitary extract, gives favourable results in this condition. Prostigmin is an example of a synthetic drug obtained as the result of a long series of researches, and it appears to possess certain specific properties of considerable therapeutic value.

CHLORINATING OUTFIT FOR BATHS

The need for keeping the water of swimming pools "sweet" has led to the adoption of various chlorination processes, but the operation is often conducted in a haphazard manner, and an excessive amount of chlorine in the water has resulted in painful conditions of the eyes, nose, mouth, and throat.

The British Drug Houses Ltd., Graham Street, City Road, N.1, have issued a pamphlet describing an outfit and a new reagent for the accurate determination of residual chlorine in water which has been purified by chlorination. One of the advantages of the method is that it can be operated by a swimming-bath attendant without difficulty. Attention was directed to the B.D.H. "chlorotex outfit" by Professor P. S. Lelean, at the annual meeting of the British Waterworks Association (*Lancet*, June 30th, 1934, p. 1428).

LONDON MEDICAL SCHOOLS AND L.C.C. HOSPITALS

CO-OPERATION IN TEACHING

The Hospital and Medical Services Committee (the successor to the Central Public Health Committee) of the newly constituted London County Council was appointed on March 30th, 1934, with Mr. Somerville Hastings, F.R.C.S., as chairman. It is responsible for the whole of the L.C.C. hospital service (except mental hospitals), comprising about 40,000 beds. At an interview on June 7th between this committee and representatives of the London Voluntary Hospitals Committee, of which Lord Riddell is chairman, a friendly discussion took place as to the relations between the two bodies. The need for early exchange of information about proposed alterations and extensions was fully recognized, and it was agreed that closer co-operation between the municipal and voluntary hospital authorities is desirable in the public interest; hospital requirements in various districts should be jointly envisaged and joint arrangements made for supplying them.

LINKING-UP ARRANGEMENTS

Arrangements for the linking up, for educational purposes, of certain municipal hospitals with the London medical schools, foreshadowed in the London Voluntary Hospitals Committee's last report, have been established. The undergraduate teaching hospitals of the metropolis are now associated with one or more of the London County Council's hospitals as follows:

- Charing Cross, with St. Charles's (Ladbroke Grove).
- Guy's, with Lewisham (S.E.), St. Allege's (Greenwich), and St. Olave's (Rotherhithe).
- King's College, with St. Giles's (Camberwell) and Dulwich (East Dulwich Grove).
- London, with St. Peter's (Stepney) and Mile End (Bancroft Road).
- Middlesex, with Archway (Highgate).
- Royal Free, with Highgate (Dartmouth Park Hill), St. Mary, Islington (Highgate Hill), and St. Pancras (Pancras Road).
- St. Bartholomew's, with Hackney (Homerton) and Bethnal Green (Cambridge Road).
- St. George's, with St. Mary Abbots (Kensington).
- St. Mary's, with Paddington (Harrow Road).
- St. Thomas's, with Lambeth (Brook Street).
- University College, with St. Mary, Islington.
- Westminster, with St. Stephen's (Fulham Road).

The arrangement is that clinical demonstrations are given at the linked hospitals as shown in the accompanying sketch map. Special facilities have been provided for instruction in obstetrics. Students at voluntary hospitals are now enabled to reside for a fortnight at municipal hospitals, during which period approximately ten cases are allotted to each student. Arrangements have been made between St. Thomas's and St. James's;

the London and Mile End; St. George's and Lewisham; and St. Bartholomew's and St. Giles's, Camberwell, and St. Andrew's, Bow. These arrangements are subject to review. The London County Council hopes in time to extend facilities for this class of teaching.

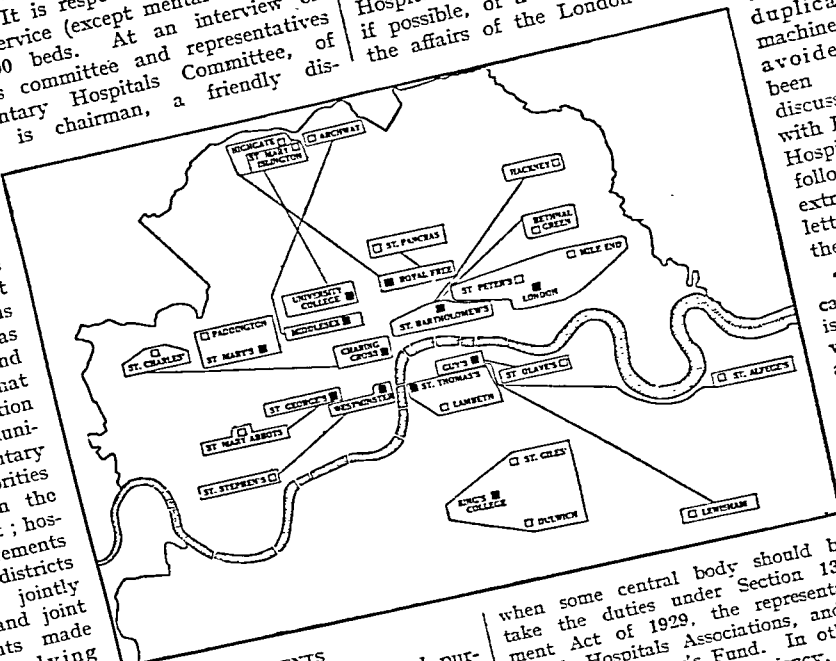

A CENTRAL COMMITTEE FOR VOLUNTARY HOSPITALS

The report issued on July 27th by the London Voluntary Hospitals Committee, from which the above information is extracted, refers also to conferences that have taken place lately between representatives of that committee and the London Regional Committee of the British Hospitals Association, with a view to the establishment, if possible, of a strong central committee to deal with the affairs of the London voluntary hospitals, in order that the present duplication of machinery may be avoided. It has been decided to discuss the proposal with King Edward's Hospital Fund. The following is an extract from a joint letter addressed to the King's Fund:

"The present duplication of machinery is inefficient and involves waste of time and effort. There is a strong feeling among members of both committees that, in view of the development of municipal hospital services, the time has arrived when some central body should be established to undertake the duties under Section 13 of the Local Government Act of 1929, the representation of London on the British Hospitals Associations, and other work not already done by the King's Fund. In other words, it is felt necessary, in the interests of efficiency, that the voluntary hospitals should be represented by an elected executive committee to take the place of the two existing bodies, and comprising adequate medical representation."

It is hoped, the report states, to present a scheme in due course for consideration by the two committees.

The first meeting was held on July 27th of the Departmental Committee appointed by the Minister of Health to report on materials and methods of construction suitable for the building of flats for the working classes, with special reference to efficiency and cost. Mr. Geoffrey Shakespeare, the Parliamentary Secretary, greeted the members, and said that their work would be of great importance in relation to the new housing proposals of the Government. Under the Bill to be introduced in the autumn, encouragement would be given to the building of flats for the replacement of slums and the relief of overcrowding. He expressed the hope that the committee would present an interim report before Christmas, so that an authoritative review of the terms of the Bill of construction would be ready when the terms of the Bill became effective. Sir George Humphreys (chairman) and all the members of the Departmental Committee were present. A programme of work was decided upon, and several subcommittees were set up to deal with particular aspects.

British Medical Journal

SATURDAY, AUGUST 4th, 1934

THE BOURNEMOUTH MEETING

Annual Meetings come and go, but the enthusiasm of those who take part in them never flags, and it is the boast of many a member that he has not missed one since his first attendance. Such a tribute to the popularity of B.M.A. Meetings must be gratifying to the presidents and local honorary secretaries who have made these yearly assemblies such an outstanding feature of the scientific, political, and social life of the medical profession, and doubly so to those who made the present gathering such a happy combination of work and festivity. Bournemouth was lavish in its hospitality, and the civic authorities vied with the Bournemouth Division in providing for their guests every variety of entertainment, from mannequin parades and cocktail parties to Bernard Shaw and Shakespeare, from excursions by road and water to Sir Dan Godfrey and his orchestra. Our thanks are due to the energetic committees and their officers whose preparatory spade-work made the machinery of organization so little visible. If we deeply regret the unfortunate circumstances that prevented Mr. F. W. Ramsay from accepting the post of President, we can at least congratulate ourselves on the man who at a relatively late hour took upon himself the arduous responsibilities of this office. Dr. S. Watson Smith, ably seconded by his charming wife, proved to be the ideal host, always attentive to his guests but unobtrusive himself: his reception at the Pavilion on Tuesday night was the most enjoyable of many magnificent entertainments, and will long be remembered by those who were fortunate enough to be present. To mention by name all those who gave the President such generous support in making the Annual Meeting of 1934 a brilliant success is not possible, but we would like to record here our appreciation of the services of Dr. O. C. Carter, the local general secretary, of Dr. E. Burstal, the science secretary, of our new Chairman of Council, Dr. E. K. Le Fleming, and of the Mayor of Bournemouth, Alderman J. R. Edgecombe.

A native of Bournemouth was asked what he thought of the procession to the church: "Fine," he replied; "but if you'd only had a band you'd have had the whole town out to watch it." This naïve conception of the significance of medical pageantry nevertheless throws a sidelight on the significance of Bournemouth. Bournemouth is first and foremost a health resort, famed for its airs, waters, and places. It is, however, in the minds of many, a town of the utmost decorum, and inhabited largely by sedate and grave people who promenade its streets in Bath chairs. This conception is erroneous. We are not suggesting that Bournemouth has "gone gay," but, like the native, it has realized

that gaiety is compatible with dignity, and that airs and waters are best served with some of the lighter but none the less valuable adjuncts to a health cure. At a time when British health resorts are beginning to come into their own, and when some critics express doubts whether Britain is so good at providing for the lighter side of life as some of our more mercurial friends on the Continent, it was most opportune that Bournemouth, whom some have looked upon as the maiden lady of seaside resorts, should have had this opportunity of showing her paces. Boredom is not mentioned in the indexes of medical textbooks, but as a chronic complaint it is as devitalizing as the other long-continued maladies we discourse about so learnedly. Bournemouth has a remedy for this no less effective than its therapies for catarrhs, rheums, and windy spasms. Nor must we forget Poole and Christchurch, the former with its feet firmly planted in the past but its head busy with modern ideas of development; the latter preserving ancient memories of Roman and Saxon invasions and recording in the walls of its church the noble history of Gothic architecture.

There were, of course, away from the main stream of this steady flow of hospitality, a few quiet backwaters in which men worked and manoeuvred their craft with varying degrees of skill. The representatives, stimulated no doubt by the airs and waters of Bournemouth, showed such a zeal for work that time was apt to take its flight on the wings of eloquence, until brought to earth by a neatly barbed bolt from the cross-bow of the Chairman, who on more than one occasion had to say, "The hopeless word of never to return, breathe I against thee." Nevertheless, those who were new to the procedure of the Representative Body were impressed by the amount of work got through and by the representative nature of its decisions. *Vox populi* may at times have shown its disagreement with *vox dei*, but as an example of democracy in the working the Representative Meeting of 1934 was instructive. The fresh influx of visitors on the Tuesday reminded one that remedies new and old were once more to be discussed, and that the Scientific Sections were again meeting to report on the year's harvest of medical knowledge. Those who had slept little during the previous four days gained some comfort from Lord Horder's dictum that most people sleep too much, while those who had headaches did not hesitate to put them down to eye-strain. It is significant that the best-attended Section meeting was that of Neurology, Psychological Medicine, and Mental Diseases, and the choice of the subjects for the Wednesday and Friday meetings—on narcotics and on pain respectively—shows quite clearly why this was so. The alleviation of mental distress and physical pain is still the chief concern of the practising physician, for these are the two symptoms most dreaded by the patient. The preventive side of medicine was well to the fore, and the discussions on ante-natal care and immunization against the specific fevers gave evidence of a lively concern in these matters.

Aug. 4, 1934]

EMERGENCY TREATMENT FOR ROAD ACCIDENTS

[THE BRITISH
MEDICAL JOURNAL] 213

One Annual Meeting leads to another, and already the bookings for the passage to Australia next year are mounting up. A tour on the grand scale awaits those who are wise enough to take such a unique opportunity of seeing the world on their way to the other side. Those who are not so fortunate will be able to dwell on happy memories of Bournemouth.

EMERGENCY TREATMENT FOR ROAD ACCIDENTS

For a number of years the medical profession and the hospitals have borne a considerable, increasing, and in many cases thankless, burden in rendering emergency treatment for those injured on the roads. It is to be hoped that now, with the Royal Assent signified to the Road Traffic Bill of 1934, the enforcement of Clauses 13 and 14 will, in securing the proper remuneration of doctors for such services, achieve an object for which the British Medical Association has long laboured in vain. As far back as 1920 the Representative Body fixed a scale of suitable fees—10s. 6d. for a night call and 7s. 6d. for a day call—payable to practitioners who were called by the police to provide emergency treatment for road accident cases. Since that time there has been a threefold increase in the number of such cases examined, and the pressing nature of the problem caused the Association to obtain, in 1930, statistics from a large number of doctors as to their experience in dealing with these cases. The figures revealed a regrettable state of affairs. Practitioners, who were morally, if not legally, bound to answer these calls for assistance, were receiving payment for their services in as little as one out of every five cases—one doctor reported 100 cases dealt with in a year with only four fees paid.

It is obviously difficult after a road accident to assign responsibility; often the unfortunate doctor who, in the emergency, has done his best for the injured party, finds himself unpaid and perhaps abused when the question of a fee is raised. Furthermore, he may be out of pocket in respect of splints, bandages, and dressings supplied, while the aftermath of cases brought to his surgery may comprise damage to furniture, and carpets and floors stained with blood, dirt, and debris. Again, emergency calls may involve relatively long journeys at night, often in inclement weather, and sometimes on feeble pretexts. Finally, on Sundays in the summer when, throughout the country, or at all events near the great arterial trunks, road massacre reaches its peak, the medical practitioner is often afraid to leave his home for fear of missing accident calls. Such is the doctor's case.

Although on Home Office instructions the local police authority is justified in paying a fee where an officer has called a practitioner to attend a road accident case, not only is such an arrangement recognized by only a small proportion of police authorities, but it often happens that the doctor is summoned by someone other

than a police official, and consequently has no redress as regards fees. In 1930 the British Medical Association approached the Ministry of Health with the suggestion that road accident cases should be regarded as "necessitous persons," and as such should require the assumption of liability on the part of county and county borough councils in respect of payment of fees to doctors attending them. This was refused. Subsequently the Association approached a representative group of accident insurance companies to point out a common ground of interest in securing adequate and immediate medical examination after motor accidents as a guarantee against subsequent claims of an avoidable character. This again was unsuccessful. The Association's work was continued in 1933, when it submitted a memorandum outlining the doctors' and hospitals' case to a select committee of the House of Lords in reference to Lord Danesfort's Road Traffic (Compensation for Accidents) Bill, and when its representatives gave evidence before the select committee on Lord Moynihan's Road Traffic (Emergency Treatment) Bill.

We are here concerned, however, with the results which have been obtained with the introduction of the emergency treatment clause into the present Act—the Road Traffic Act of 1934. On November 9th, 1933, the select committee of the House of Lords reported for a second time on Lord Moynihan's Bill for payment of fees to doctors for emergency treatment, the Bill being the outcome of co-operation between its introducer and the B.M.A. Early in 1934 the Parliamentary Medical Committee discussed with Lords Moynihan and Dawson the question of compensation to doctors and hospitals for treating motor accidents, and a deputation waited upon the Ministry of Transport to discuss this question. The substance of Lord Moynihan's Bill was eventually incorporated into the Road Traffic Bill, 1934, and, with one or two minor amendments, was reported to the House of Commons and passed to the Lords. On July 10th Lord Plymouth indicated the Government's acceptance of this emergency treatment clause, and the report stage was concluded on July 24th.

Briefly, the relevant clauses of the present Act—Nos. 13 and 14, the emergency treatment clauses—enforce the following conditions. Where medical or surgical examination is immediately required as a result of injury to a person caused by, or arising out of, the use of a motor vehicle on the road, the person using the vehicle must pay the doctor first rendering emergency treatment a fee of 12s. 6d., plus travelling expenses of 6d. a mile or part of a mile over the first two miles travelled. The liability of a person using the vehicle stands even if the accident resulted from "the wrongful act of another person." The police are to assist in the identification of the vehicle and its user. Claims by a practitioner or hospital for fees due can be made orally at the time when treatment is rendered, or in writing served on the user of the vehicle within seven days. The application must be signed by the claimant or the executive officer of the hospital, must

state the circumstances in which the treatment was rendered, that it was effective, that it was rendered by the claimant or in the hospital, and that the claimant or hospital was the first to carry out the treatment. The claim in writing can be delivered to the user of the vehicle or sent to him in a prepaid registered letter at his usual or last known address. The sum is recoverable as a simple contract debt, and its payment operates as a discharge of liability on the part of the vehicle user to pay any (further) sum in respect of emergency treatment.

To what extent the enforcement of the Road Traffic Act of 1934 will ensure fair recompense for doctors and hospitals expending their time and energy in giving emergency treatment for road accident cases remains to be seen. We can at all events hope that the labours of the British Medical Association and the profession have not been in vain. It may not be out of place to indicate that the success attending the movement to remunerate doctors for road accident services has been largely due to the unremitting efforts of the Association during the last decade, and to record the thanks of the Association to the Parliamentary Medical Committee, with particular reference to its chairman, Sir Francis Fremantle, and its secretary, Dr. A. B. Howitt.

SIR HENRY BRACKENBURY

Among those engaged in the central work of the British Medical Association it has long been an open secret that Sir Henry Brackenbury would not seek re-election as Chairman of Council at the Bournemouth meeting. Their regret will be shared by every member who knows anything of the political and administrative work of the Association since the war. Sir Henry has given time and energy to its service without stint. When he entered the inner circle of the Association he had behind him long experience in municipal and educational affairs. In the course of twenty years' membership of the Council he has held office as Chairman of the Insurance Acts Committee for nine years, Chairman of the Representative Body for three years, and since 1927 Chairman of Council. During his long tenure of the chair of the I.A.C. Dr. Brackenbury was the chosen spokesman for the medical profession before the arbitration tribunals which settled the insurance doctors' capitation fee, and his brilliant advocacy on those occasions will long be remembered. When he was in full professional harness it was always a marvel how he managed to get through so much public work of high importance while carrying on the exacting duties of general practice. His grasp of a subject and his rapid analysis of the points involved, his logical mind and power of marshalling facts in order to present a case, have been combined with an unusual capacity for work and a natural gift of leadership. All will be glad to know that Sir Henry Brackenbury's services will continue to be at the disposal of the Association, and with him they will welcome the Council's choice of his successor. Dr. E. K. Le Fleming has graduated with the highest honours through two major chairmanships—that of the Panel Conference for five years, and that of the Representative Body for the past three years.

THE PATHOLOGICAL MUSEUM AT BOURNEMOUTH

The Pathological Museum, arranged in connexion with the Annual Meeting of the Association at Bournemouth, was conveniently housed on the lower floor of the Municipal College, the building in which the Sectional meetings were held each morning. A rare collection of pathological specimens were arranged on benches round each room, with a large number of microscope preparations on tables in the centre. The pathological specimens were grouped on an anatomical basis, and consisted chiefly of unusual lesions and "curiosities," many of which excited considerable interest. The nature of each specimen and the name of the exhibitor were announced in the catalogue. The Museum Committee expressed its appreciation in particular to the following colleges and hospitals which lent material for the museum or were responsible for exhibits: the Royal Army Medical Corps, the University of Edinburgh, Bethlem Royal Hospital, St. Mark's Hospital, St. Bartholomew's Hospital, Westminster Hospital, St. George's Hospital, the South Devon and East Cornwall Hospital, and the Cancer Hospital, London. The Museum included also a number of special exhibits, some of which were intended to illustrate subjects discussed in the Scientific Sections. These comprised a series of specimens and photographs arranged by Dr. C. Lovell from the Bethlem Royal Hospital, London, showing progressive pancreatitis in relation to mental states. Workers at the Cancer Hospital, London, had on view a series of malignant tumours of skin and connective tissues of mice and rats produced by methylcholanthrene, a transformation product of the deoxycholic acid of bile, and a number of specimens demonstrating the effects of oestrin in the genito-urinary system of mice. Dr. Haddow, from Edinburgh University, arranged a series of sections showing cellular transplantations of fowl sarcoma. Amongst items of more general interest may be mentioned a series of ophthalmological colour drawings, instruments, and books exhibited by Mr. Arnold Sorsby; the clinical picture gallery arranged by Dr. S. Watson Smith; the pedigree charts of families affected by polyposis intestini, shown by Dr. Cuthbert Dukes; and a series of pulmonary specimens of surgical interest lent by Mr. George Mason of Newcastle-upon-Tyne. The excellent selection and disposition of the specimens in the Museum was commented on by many of the visitors who came to look round, and it was obvious that the Museum Committee had given to this undertaking a great deal of thought as well as hard work.

ORGANIZED MEDICAL CARE

Medical politicians and publicists in this country who are free from *Schadenfreude*—and that, we hope, means all of them—will read with sympathetic interest a leading article in the *Journal of the American Medical Association* for July 14th on "Organized Medicine and Medical Care." Its subject is the attitude of the organized profession in the United States towards proposals "to put over a system of social medicine"—that is, to introduce a scheme of national health insurance. Its main purpose is to disabuse anyone of the idea "that the American Medical Association, representing 100,000 physicians in the United States, is

opposed to all change in the nature of medical practice or to properly controlled experiments in providing medical service that may be set up in any city, county, or State." A subsidiary purpose is to deprecate the action taken by the American College of Surgeons at Chicago on the eve of the annual session of the A.M.A. in Cleveland, at which the whole profession proposed to consider this matter. Remembering the events of 1911-12 in Britain we can well understand the alarm felt lest the medical profession of the United States should come to grief through divided counsels. On June 12th last the House of Delegates of the A.M.A., following a long executive session, set forth ten principles to guide medical practice and to form the basis for any experiment that might be contemplated. These principles have been published by our temporary in its issue of June 30th (p. 2200). So far as we can judge at this distance, nine of the ten principles could be made to fit into a State system of national health insurance or into any scheme for a public medical service organized by the profession itself. They were planned, we read, "to circumvent the interest of politicians, commercial promoters, and propagandists whose activities in relationship to new forms of medical practice are not wholly unselfish. . . . They will maintain the personal relationship between physician and patient, which keeps medicine a profession. On the principles adopted by the House of Delegates the American medical profession must stand, and in their favour it must speak with a united voice." Then follow some general remarks not wholly flattering to "socialized medicine" in European countries, and the article ends with this exhortation: "Let us consider carefully, act with caution, reserve judgement, and speak with one voice for the truth."

PERIOD OF ISOLATION IN SCARLET FEVER

Following on the decline in severity of scarlet fever in past years, and the demands on fever hospital beds for the admission of cases of measles, whooping-cough, pneumonia, and puerperal fever, it has become necessary to consider whether the most economical use is being made of the accommodation now at our disposal. The various problems arising out of these cognate subjects are not new, and progressive medical officers of health have not hesitated to apply the Ministry of Health recommendations set out in the 1927 report, No. 35, on the administrative aspects of scarlet fever. Many authorities have effected considerable savings in bed accommodation by the selection of cases of scarlet fever for admission to hospital and by shortening the period of minimum detention of "clean" cases to four, and even in a few cases to three, weeks. The matter has, however, not been allowed to remain at this point, and on page 1047 of our issue of June 9th we reported some observations by Dr. H. S. Banks, who claimed that by the early intravenous administration of an adequate dose of scarlet fever antitoxin it was practicable to shorten the period of isolation in hospital to two or three weeks in the great majority of cases. As a safeguard he suggested that patients should be seen once at least at an out-patient clinic before returning to work or school. The question of the period of isolation in scarlet fever has recently also been the subject of

consideration by J. E. Gordon and G. F. Badger¹ of Detroit, but from a somewhat different and perhaps less heroic angle. Dr. Gordon has been interested in all aspects of the administrative control of scarlet fever for several years, and a series of thoughtful and painstaking papers testify to the care and thoroughness with which he has approached the problem. Administrative practice in the U.S.A. with regard to that applied scarlet fever corresponds fairly closely to that applied in Great Britain, although there greater emphasis is laid on home isolation, but, as the authors point out, this has largely been built up empirically with general rules for all patients irrespective of individual variations in severity of attack or probable degree of communicability. In order to make our policy more scientific, they urge concentration on the individual case; and in order to evolve a system which will render this more logical have made a careful study of the factors which determine the persistence of infection in those persons who have become responsible for return cases. In common with others they believe that little is to be gained by laying down bacteriological standards of freedom from infectivity, and find that the incidence of secondary cases depends on the age of the original patient, the presence or absence of complications, and the season of the year. In Detroit, during 1929, in which a minimum period of four weeks' isolation was maintained for all patients, the infecting case rate for persons over 15 was 0.5 per cent., and for children under that age 5 per cent. Since that time various minimal periods of isolation have been tried, modifications being introduced to allow for season and the age of the patient, and in the last complete year—1933—persons under 15 years were detained for four weeks from January 1st to June 30th, and for three weeks from July 1st to December 31st. Those over 15 years were kept in hospital for three weeks in the former half-yearly period, and only two weeks in the latter. The infecting case rate did not increase, and the relative frequency as between adults and children was not disturbed. During the whole of 1934 adults are to be retained for only two weeks and children for three, and the results of this departure will be awaited with interest. Gordon and Badger are fully aware that the purely preventive necessities of the case may not coincide with those involved in its medical management, but the decrease in the period of isolation resulted in no deleterious effect from either standpoint. The economic saving was appreciable, approximately 9,000 isolation days being saved for all scarlet fever patients in 1933, a reduction of 30 per cent. Modification of the detention period, as the authors are careful to emphasize, must be correlated with the type of scarlet fever present, and when the disease is severe in character longer periods of isolation may become necessary. The time may have arrived in this country when a careful trial might be made in selected areas of this progressive policy. Scarlet fever has been unusually prevalent over the whole of Britain during the past year, and the resulting mass immunity may render the near future an exceptionally favourable time for the experiment. It is certain, however, that, to overcome the psychological inertia induced by the observance of long-established principles, a considerable amount of educative work would require to be carried out

¹ Amer. Journ. Pub. Health, May, 1934, p. 438.

among the public, both lay and medical, to prepare the way beforehand. In Drs. Gordon and Badger's paper the whole question of isolation as a measure of control in scarlet fever, both in hospital and in the home, is considered in detail. In their opinion, and as far as their experiences in America are concerned, any further improvement in the control of scarlet fever by isolation will be the result of earlier isolation, and in cases kept at home more rigorous standards, especially during the first week of the disease. The authors reveal themselves strong advocates of the policy of home isolation, and mention the interesting fact that, while an irreducible minimum of cases will always require hospital accommodation, in American cities this will not often exceed a quarter of the whole. Medical officers of health in this country, confronted with the present-day standards of housing, will read this with envy.

CARDIAC HYPERTROPHY IN ANAEMIA

Severe anaemia is one of the less common causes of cardiac hypertrophy; it is rarer still since the discovery of an effective treatment for Addisonian anaemia. In an interesting discussion of this problem L. Boucut and R. Froment¹ point out that very low haemoglobin levels have been most often seen in pernicious anaemia, and necropsy has shown in such cases that heart weights are often moderately increased—for example, to 400 or 500 grams, and occasionally more—the hypertrophy involving both ventricles. The cardiac hypertrophy appears to vary directly with the severity and duration of the anaemia; and although the change has been most often seen in the pernicious type, any secondary anaemia, provided it is severe and prolonged enough, may give rise to it. Gross heart failure with oedema, effusions into the serous sacs, congestion of the lung bases, and a rapid regular pulse has been seen in the course of the disease; it is reported as occurring in one of the author's cases in which liver therapy failed, the symptoms of failure being temporarily relieved by digitalis. Commenting on the mechanism of the cardiac enlargement of high-grade anaemia, the authors agree with those who have regarded it as a work hypertrophy. Several observers have demonstrated that when the oxygen-carrying capacity of the blood is low, as in marked anaemia, the cardiac output and the speed of the circulation are considerably increased. It has been shown, however, that there is no appreciable increase in the output until the haemoglobin falls below 50 per cent. Of the two possible ways in which an increased volume of blood can be pumped by the heart—namely, an increase in rate and a greater output per beat—it is thought that the latter is much the more important, acceleration in rate being usually moderate. The compensatory increase in circulation rate makes life, and even some degree of effort, compatible with a greatly reduced oxygen-carrying capacity of the blood. For example, acute reduction of this capacity (say to 30 per cent.) in carbon monoxide poisoning leaves no time for compensatory mechanisms to develop, and death quickly supervenes. The authors consider that the anoxaemia of chronic lung disease may similarly increase the output of the heart and therefore its work: this explains the cardiac hypertrophy sometimes seen

in these conditions, especially when the hypertrophy affects both sides of the heart. In support of this are the fast circulation rates which have been reported in chronic lung disease. Another disorder of the heart associated with anaemia is angina pectoris. Lewis and his co-workers have brought forward convincing evidence in support of the theory of myocardial ischaemia as the cause of angina, and K. Paschkis,² alluding to their work, suggests that if relative local anoxaemia or ischaemia can cause angina, then a severe anaemia, with diminished capacity of the erythrocytes for conveying oxygen, may be expected, in combination with other factors, to favour the occurrence of anginal attacks. Varying reports have been given concerning the frequency of angina in pernicious anaemia: Lewis states it to be common, and others have reported it in from 2.7 to 8 per cent. of cases. Paschkis describes four cases of angina in severe anaemia: in three, efficient treatment of the anaemia led for very considerable periods to disappearance of the angina. One patient had pernicious anaemia and auricular fibrillation; another, pernicious anaemia with little objective cardiopathy; the third, secondary anaemia from menorrhagia, with syphilitic aortic disease.

THE FIRST PARATHYROIDECTOMY

J. Bauer and R. Kienböck,² in a combined clinical and radiological study, give a further account of the patient in whom Mandl in 1925 removed, for the first time in bone disease, a parathyroid adenoma. At that date the diagnosis of (Recklinghausen's) generalized fibrocystic osteitis was made; the patient, a male aged 39, had deformity of the left half of the pelvis, the left femur and foot, and the right knee. Very considerable improvement followed parathyroidectomy, and in many countries removal of parathyroid tumours has apparently led, in similar as well as dissimilar cases of morbid bone conditions, to equally favourable results. In their contribution Bauer describes a recurrence of disabilities in Mandl's patient, and Kienböck maintains that the condition was one of Paget's disease (osteitis deformans). The patient became worse six years after the operation, and was unable to walk: he had calculi in the right renal pelvis and a negative calcium balance, with greatly increased urinary calcium excretion and diminished muscle and nerve excitability. In view of the renewed hyperparathyroidism the gland was given therapeutic irradiation, and later another adenoma was sought but not found. An excised portion of thyroid, however, contained two microscopical foci of normal parathyroid tissue, and the continued presence of hyperfunctional but inaccessible areas of parathyroid was inferred. Among the reasons assigned by Kienböck for diagnosing this case as one of Paget's disease are: the characteristic radiological findings of diffuse thickening and malacia, with a characteristic admixture of porosis and sclerosis; the chronic course, with preservation of good general health; the affection of the parts near the ends of the long bones; and the normality of the skull and certain other bones. He admits that the finding of a parathyroid adenoma in Paget's disease is very rare. The

NEW AND NON-OFFICIAL REMEDIES

patient's sister suffered from the same disease in a typical form: familial incidence has not been described in Recklinghausen's disease. Kienböck does not agree with those who consider Recklinghausen's and Paget's diseases as identical. For Paget's disease he suggests the name multiple (osseous) scleromalacia, while conceding that occasionally the skeleton is affected in solitary foci. Recklinghausen's disease he would call multiple (osseous) cystofibroma, with generalized and, occasionally, solitary forms.

UNDULANT FEVER IN AUSTRIA

V. Russ has lately published a table¹ which covers the period 1929-33 (up to July 1st), during which altogether 7,403 sera were sent him for examination. All were examined for agglutination of Bang's bacillus. Some of the sera had been sent to the laboratory with a specific request for examination for undulant fever alone; and in this category there were sixty-two positive and 916 negative sera. Among the sera sent in for the diagnosis of fever of the typhoid group, there were sixty-eight in which only Bang's bacillus was agglutinated, and thirty-four in which it was more easily agglutinated than other bacilli. Thus, with a total of 164 positive sera, the proportion of Bang-positive cases was 2.2 per cent. In a second table the author publishes the findings of various investigators in Germany, Denmark, Estonia, Norway, and the U.S.A., with regard to the proportion of human positive samples of milk; and he notes that, considering how great this proportion is, the susceptibility of human beings to this infection must be comparatively slight in view of the paucity of definitely established human cases. In Germany, for example, only 626 cases were notified in 1929, 428 in 1930, and 498 in 1931. In the absence of compulsory notification in Germany, these figures do not, however, tell the whole story. Although pasteurized milk has been convicted of still harbouring Bang's bacillus, this finding does not reflect on pasteurization itself, but on the carelessness of the persons handling the milk in question. The author is sceptical as to contact infections, from one person to another, and he considers infected animals as the main and practically exclusive source of the disease in human beings.

NEW AND NON-OFFICIAL REMEDIES

We have received from the American Medical Association two of its annual publications—namely, *New and Non-Official Remedies, 1934*,² and the report for 1933 of the Association's Council on Pharmacy and Chemistry.³ The latter volume contains the findings of fact upon which changes in the former are based. In recent years the policy has been adopted of grouping together a number of articles having a similar action and introducing the group by a general discussion. The effect of these changes is to increase the value of *New*

¹ *Wien. klin. Woch.*, March 9th, 1934, p. 289.
² *New and Non-Official Remedies, 1934*. Containing Descriptions of the Articles which stand accepted by the Council on Pharmacy and Chemistry of the American Medical Association for 1934. Chicago: 535, North Dearborn Street.
³ Annual Report of the Reports of the Council on Pharmacy and Chemistry of the American Medical Association for 1933. With the Comments that have appeared in the *Journal of the A.M.A.*

and *Non-Official Remedies* as a work of reference, and it constitutes an excellent guide to reputable extra-pharmacopoeial preparations. The report of the Council on Pharmacy and Chemistry consists chiefly of short articles explaining the reasons for the refusal of new preparations. Some of these make amusing reading, and help to explain how clinical evidence in support of new remedies is obtained. For example, an article "On examination, a large part of this article was found to be identical, word for word, with a section of an advertising booklet issued by the English firm . . . ; the remainder of this uncritical effusion is devoted to completely uncontrolled clinical evidence of the same sort as that presented in the advertising material." The volume also includes some interesting reports on important problems regarding which the evidence is still obscure. The most important of these is a twenty-five-page review of the therapeutic effects of oestrogenic substances. The Council concluded that the future of sex hormone therapy appears promising, but that at present clinical practice has far outrun scientific information, and that the subject is unlikely to advance until the basic facts are more firmly established.

RADIOLOGICAL TREATMENT OF CANCER: LEAGUE OF NATIONS CONFERENCE

On the occasion of the fourth Radiological Congress, now being held in Zurich, the Health Organization of the League of Nations has convened an expert conference to advise on the further prosecution of the international inquiry into the results of the treatment of uterine cancer by radium and x rays which was put in hand at Geneva in consequence of the report made by its Radiological Commission in 1929. At this conference, which met from July 21st to 23rd, Sir George Buchanan and Dr. Boudreau represented the Health Committee of the League, and the experts attending included Sir Comyns Berkeley and Colonel A. B. Smallman (England), Professor Lacassagne (France), Professor G. Forssell and Dr. Heyman (Sweden), Professor van Roooy and Dr. Jansen (Holland), and Professor Murdoch (Belgium). The conference recommended that statistical statements with commentary should be annually issued, beginning with 1936 and relating especially to survivals for a minimum period of five years after the initial treatment. The principal object of these statements is regularly to present statistical information regarding the results obtained by the application of radiotherapy to patients suffering from cancer of the cervix at different stages when certain agreed rules for the preparation and compilation of the data have been observed. It is proposed to obtain the data through special correspondents in different countries, and to have the annual statements prepared under the advice of a small expert advisory council appointed by the Health Committee of the League.

We have to announce with regret the sudden death, at Oxford, of Dr. M. S. Pembrey, F.R.S., late professor of physiology in the University of London at Guy's Hospital Medical School.

ONE HUNDRED AND SECOND ANNUAL
MEETING

of the

British Medical Association

HELD AT BOURNEMOUTH, JULY, 1934

THE SECTIONS

SUMMARY OF PROCEEDINGS

During the next few months there will be published in the BRITISH MEDICAL JOURNAL the opening papers communicated to the Scientific Sections of the Annual Meeting at Bournemouth. The reports of discussions in this and successive issues are intended to give members who were not present a general idea of the proceedings.

SECTION OF MEDICINE

Wednesday, July 25th

CLINICAL IMPORTANCE OF ACHLORHYDRIA

With Professor LANGDON BROWN, the President, in the chair, Dr. ARTHUR F. HURST opened a discussion on the clinical importance of achlorhydria.

Dr. Hurst first discussed the various functions of the gastric juice. The most obvious was the secretion of pepsin and its activation by hydrochloric acid; this was a useful but not an essential function. More important was the antiseptic action of the acid; not only was this effective in the stomach itself, but it had an action lower down, for diminished acidity in the small intestine (a condition to which achlorhydria predisposed) favoured the growth and spread of *B. coli* from the colon. Evidence was accumulating to the effect that many symptoms hitherto ascribed to the stomach or colon were really due to disorders of the small intestine. Gastric juice also had important functions in connexion with haemopoiesis. Achlorhydria was frequently associated with failure to deal adequately with the iron in an ordinary diet, with a resulting microcytic anaemia, and there was the more definite failure to produce the intrinsic factor which was the fundamental fact in pernicious anaemia. It also produced an enzyme which he called "neuopietin," absence of which led to degeneration of the posterior and lateral columns of the spinal cord. Ten per cent. of people secreted less hydrochloric acid than their fellows, and the majority of these developed achlorhydria and its associated troubles: this was generally due to chronic gastritis as the result of prolonged mechanical or chemical irritation. Dr. Hurst then discussed the effects of gastritis on the gastric juice, attributing to excess of mucus a large share in the production of achlorhydria. Post-operative achlorhydria following gastro-enterostomy was usually caused by gastritis antecedent to the operation, or in some cases to a severe gastritis set up by an excess of bile in the stomach. The association of achlorhydria with carcinoma of the stomach was again really the result of gastritis present before the growth developed, and he knew of no case in which free acid, if present when the growth was discovered, had been observed to disappear with the growth of the cancer. He had long believed that cancer never developed in a healthy stomach, and that in 75 per cent. of cases it began in a chronically inflamed mucous membrane, usually associated with achlorhydria. If his views were correct, it was clear that the main effort in achlorhydria must be to remove the gastritis, and in his hands 82 per cent. of patients, when treated with this end in view, resumed their acid secretion. Dr. Hurst concluded by picturing a future

in which, with prophylaxis of gastritis or its adequate treatment in the early stages, carcinoma of the stomach would no more be seen. Dr. KEITH SIMPSON demonstrated specimens illustrating Dr. Hurst's points, dealing particularly with the pathological aspect. He said that post-mortem material was useless owing to the extremely rapid autolysis occurring after death.

Dr. JOHN F. WILKINSON (Stockport) said that many cases of achlorhydria were only apparent, and when investigated with histamine showed free hydrochloric acid. In contradistinction to American workers, he had demonstrated that histamine stimulated enzyme as well as acid production, pepsin and haemopoietin being more important than acid. The main symptoms associated with achlorhydria were flatulence, nausea, and diarrhoea. In a series of 135 cases of chronic diarrhoea, 32 per cent. had achlorhydria. Sore tongue was also a common complaint, and of forty-seven cases 25.5 per cent. had achlorhydria. It was important to treat these cases, as carcinoma and pernicious anaemia might develop. Of cases resembling pernicious anaemia, but with free acid in the gastric juice, some showed a persistently high reticulocytosis and did not respond to liver treatment, and the prognosis was unfavourable. Haemopoietin production was more important than that of acid and pepsin, and normal people with achlorhydria, when placed in circumstances unfavourable to haemopoietin production, might then develop pernicious anaemia.

Dr. C. C. UNGLEY (Newcastle-on-Tyne) dealt with the defects in gastric function connected with absorption of food factors associated with achlorhydria. Such defects were responsible for the production of pernicious anaemia, subacute combined degeneration of the cord, and idiopathic hypochromic anaemia. Autolysed yeast had sometimes been found to produce a haemopoietic response in pernicious anaemia; this, however, only occurred if it were given by mouth, and so it owed its efficacy presumably to a content of "extrinsic" and not "intrinsic" factor. Cases giving such a response to yeast must therefore be considered to have retained the power to form some "intrinsic" factor, although they showed a histamine achlorhydria. Clinical analysis suggested that pernicious anaemia and subacute combined degeneration were really due to a lack of different substances. In idiopathic hypochromic anaemia achlorhydria was present in over 50 per cent. of cases, and there was frequently an associated defect in the secretion of pepsin, chloride, and neutral red. The nature of the defect was obscure, but as iron was utilized much more completely if injected intravenously it was probably a defect in absorption. Administration of hydrochloric acid alone had no effect. Dr. J. H. ANDERSON (Ruthin) stated that there was a mistaken tendency to think of achlorhydria merely in terms of cancer and pernicious anaemia. His method was to give an ordinary test meal, and, if no free acid appeared at the end of the first hour, to inject histamine. Of 225 cases so investigated, thirty-six received histamine, and complete achlorhydria was found in twenty of these. He reviewed the symptomatology of these twenty. Little alcohol or tobacco was taken by more than a small proportion; in very few were the symptoms complained of referred to the stomach. Acute infection was present in two cases, but chronic infection of some kind had been noted in eighteen. There was no anaemia in thirteen cases, secondary anaemia in five, and pernicious anaemia in two. No evidence supported the view that achlorhydria had any effect on the rate of emptying the stomach. Further research was needed into the incidence of achlorhydria in a large number of healthy young people, with the follow-up of the medical history for at least a generation. This would provide adequate evidence for or against the importance of achlorhydria. Dr. J. R. GILLESPIE (Belfast) recalled the beneficial effect he had seen in a cholera epidemic from giving drinks of dilute hydrochloric acid. Dr. G. W. GOODHART pointed out that in the production of achlorhydria the muscle as well as the mucous membrane played some part. He criticized Dr. Hurst's views on the effect of mucus. Mucus was a protective secretion, and produced its maximum effect at the end of digestion; it was quite powerless to neutral-

AUG. 4, 1934]

THE SECTIONS: SUMMARY OF PROCEEDINGS

ize the acid in a freely secreting stomach. He protested against the growing tendency to use histamine alone as a routine test-meal stimulant. Dr. ALISON N. MACBETH asked whether there was sufficient evidence of the difference neuro- and haemo-poietin, and suggested that the difference might be in the individual susceptibility of the neural and blood systems. Dr. DOROTHY HARE asked whether any useful information could be obtained by measurement of the volume of acid secretion in ten-minute periods after histamine.

SECTION OF SURGERY Wednesday, July 25th

TREATMENT OF ARTERIAL EMBOLISM

With the President, Professor G. GREY TURNER (Newcastle-upon-Tyne), in the chair, Mr. GEOFFREY JEFFERSON (Manchester) read a paper on "The Surgical Treatment of Embolism of the Peripheral Arteries."

Mr. Jefferson said that arterial embolism was a grave emergency calling for intervention even earlier than a perforated viscus. A successful operation averted gangrene by restoration of the circulation. Carrel's experimental work on the surgery of the blood vessels, by showing that vessels could be incised and sutured without thrombosis occurring, a suitable technique being used, had paved the way for successful embolectomy. A standardized and useful addition to surgery had now been made. This in great measure due to the Swedish surgical school, led by Einar Key. In recording his own successful case in 1925 he had been able to collect from the literature seventy-three cases, of which twenty-eight had done well. Since then the literature had grown prodigiously, culminating in Danzis's detailed analysis of all cases reported up to 1933. Because of this last paper he did not propose to make a new survey, but to give an account of his personal experiences in embolectomy. Mr. Jefferson then detailed his six personal cases. Two of these were completely successful. Of these two, one was a case of embolism at the junction of the axillary and brachial arteries after operation for umbilical hernia. The other was a case of embolism at the bifurcation of the common iliac artery in a patient with auricular fibrillation. One had limited post-operative gangrene following subclavian embolectomy, whilst another had a slight degree of ischaemic contracture following embolectomy at the division of the brachial artery. The two remaining cases, both suffering from auricular fibrillation, were failures. In one of these the embolism was femoral, in the other brachial.

In the discussion that followed, Dr. MAX DANZIS (Newark, N.J., U.S.A.) stated that, as knowledge of the good results obtained by Scandinavian surgeons had spread through the United States, not only had the operation of arteriotomy for peripheral embolism become more common, but the time interval between lodgement of embolus and operation had diminished, with corresponding good results. It was important to differentiate between immediate and end results, since although 41 per cent. of cases operated upon obtained immediate post-operative circulatory restoration, about one-quarter of these patients died from subsequent secondary emboli. None the less, this showed a distinct superiority over non-operative treatment, in which 87 per cent. of patients died one to fourteen days after the onset of the disease. The causes of death in patients suffering from severe emboli leading to gangrene, cardiac decompensation, cerebral emboli, and pneumonia. He did not think operation was indicated in patients suffering from severe exacerbations of subacute endocarditis or from grave embolus of the axillary artery at the site of a previous successful operation. He favoured regional or block anaesthesia as against local infiltration, because the former allowed of a wider exposure and clearness of the operative field.

Dr. G. J. LANGLEY (Manchester) said the first duty of the physician in these cases was to decide whether operative intervention was called for, and in determining this difficult question it was necessary to be sure that a sufficiently large vessel had been occluded, that the vessel was healthy enough to permit of surgical stitching, and that the general state of the patient would admit of immediate operation. If the site and the cause of the mother thrombus could be determined a big step had been taken towards choosing cases for operation. He thought that some apparent general contraindications to operation could be dealt with adequately for its performance. High-speed auricular fibrillation could be quickly controlled by intravenous strophanthin or rectal digitalis, and diabetics made safe for operation in a few hours by glucose and insulin.

Mr. ERNEST FINCH (Sheffield) referred to the use of Key's probe for removing the embolus at a distance. His experience bore out Neuhof's statement that return of circulation did not necessarily mean that a through passage had been obtained at the site of impaction, but might mean simply the establishment of the collateral circulation. He described a successful case in which he had removed an embolus in the brachial artery by means of Key's probe through an opening distal to the site of lodgement. Immediately the clot was ejected there was free bleeding from both ends of the vessel, showing how the collaterals had become freed. The artery was then tied on both sides of the incision and divided. An exactly similar case occurred in the practice of a colleague, but in this instance the distal end of the artery did not bleed after removal of the embolus, and an unsuccessful result followed the identical surgical procedure, thus illustrating the value of unblocked collaterals.

Mr. G. E. LARKS (Plymouth) mentioned his experiences in four cases of embolism, one completely successful, the others impracticable for reasons of multiple emboli or of delay before advice had been sought. Post-operative cases were the most straightforward, and presented the greatest possibilities. He considered that embolism in auricular fibrillation occurred at the stage when normal rhythm was being restored, and that this gave hope that such cases would be given an early opportunity for surgical intervention. Finally, he discussed possible surgical procedures in cases where the operation was performed at a stage when it was likely not to prove wholly successful, and instanced ligature of the corresponding main vein.

Mr. A. G. BANKS (Ipswich) recapitulated a published successful case of brachial embolectomy in which operation was performed four hours after the onset of symptoms. The patient had since had a hemiplegia, probably of embolic origin, and had almost completely recovered from this. He considered interrupted stitches sufficient in a short wound of the vessel. Dr. BERGESTROM (Sweden) referred to the successes in the field of pulmonary embolism. Mr. E. M. COWELL (Croydon) gave an account of a case of traumatic thrombosis of the common femoral artery with no pulsation in the limb. He had removed a white clot from the vessel, and a long worm of red clot from the superficial femoral artery. The circulation returned, and the artery remained patent long enough for the collateral circulation to be established. A useful limb resulted. Mr. L. O'SHAUGHNESSY spoke of the abdominal limb successful cases of embolectomy in the abdominal aorta, and in particular of a case not operated upon in which, in addition to the usual symptoms, there was suppression of urine. Necropsy revealed that impaction had taken place at the level of the renal arteries. He suggested that in such a case embolectomy might suitably be carried out through an incision in the descending thoracic aorta. Professor A. W. SHEEN (Cardiff) related a case of double embolectomy of the common femoral arteries. The patient suffered from tertiary syphilis. Gangrene was only limited. He was unwilling to accept that aseptic thrombi would form in relation to a septic focus. Mr. ROCK CARLING said that the drawback of the cases associated with auricular fibrillation was the multiplicity of the emboli. The number of cases of paradoxical

embolism was quite considerable, and this type held out good prospect of complete success. Since emboli were associated with extensions of clot both above and below the site of impaction, on the whole it was easier to cope with such clot through a distal rather than a proximal incision. Some of the results were due to spasm of the arterioles as much as to the embolus. He thought control of the vessel at operation was best achieved by elastic or tape bands passed behind the vessel above and below the site. It did not matter much if the suture passed through all coats of the vessel. The President stressed the importance of what might seem to be a highly technical subject to the practitioner, since only by early attention could a successful outcome be hoped for.

Mr. JEFFERSON, replying, agreed that cases with active endocarditis were unsuitable for operation, and that the artery was better opened below the site of impaction. Referring to clot on the far side of the embolus, he said that in one instance, not his own, 125 cm. of clot had been removed in two portions. Such clot, he considered, did not form at once, but was not long in appearing. He always tried to put in his stitches very superficially, but agreed with Mr. Carling that it did not seem to make any difference if the suture presented a little on the interior of the vessel.

THE SEPTIC HAND

Mr. R. KENNON (Liverpool) in a paper on "The Problem of the Septic Hand," stressed the importance of the organization of special clinics with access to beds at general hospitals for treatment of cases of infected hands. The problem was threefold: prevention, diagnosis and early treatment, and the avoidance of subsequent stiffness and deformity. Regarding prevention, he considered that punctures by small objects were the commonest cause, and that such should be treated at once by removing the surface epithelium over the punctured area with a razor blade. This relieved tension, whether infective or only simple traumatic inflammation was present, and allowed egress of the products of inflammation. The pricked finger should then be kept dry or have a spirit dressing applied, and in the case of a surgeon it would be well to have a splint applied at this stage. Prevention, again, found scope in the rational treatment of trivial affections of the nails, and in this connexion he urged the retention of any part of the nail which could be conserved. These lesser conditions could assume alarming proportions if treated wrongly, by squeezing for non-existent pus and by the use of antiseptics and boiling water. Immersion of the hand in very hot water led to devitalization of avascular structures, caused cracks in the nails of the other fingers, and was a source of great pain. In the early treatment of the streptococcal finger, so common in doctors and nurses, he thought removal of the surface epithelium at the site of puncture and a subsequent hypertonic salt dressing the best local treatment. Serum therapy must be employed when rigors occurred. Mr. Kennon then dealt with the various forms of whitlow. He had found the best indication of tendon sheath involvement to be the presence of maximal tenderness at a point where the sheath ended or narrowed. No force should be employed to remove sloughing tendons; these took about a fortnight to separate. In the operative treatment of a septic hand general anaesthesia and the use of a tourniquet were essentials. Hot fomentations had their highest value after operation. Prevention of stiffness could only be done by careful timing of removal of the splint and institution of voluntary movement. The speaker reviewed the assessments for compensation in cases where stiffness had supervened in industrial cases. Amputations, apart from cases with suppurative arthritis or loss of tendon, should be delayed until at least three months had elapsed since healing. At that interval it could be determined exactly how much should be sacrificed for the patient's particular needs. Amputations were necessary in only 2 per cent. of cases.

In the discussion which followed, Mr. P. H. MITCHNER advocated the admission of all patients with septic hands to hospital, and deprecated the use of tourniquets on the

upper limb. While splintage was valuable in the early stages, it was not wise to continue this after evacuation of the pus. Early active movements were more valuable. Mr. E. M. COWELL (Croydon) thought the use of iodine as a first-aid measure should be discouraged because of its harmful action on the tissue defences. Mr. H. W. S. WRIGHT recommended liq. aluminii subacetatis (*Extra Pharmacopoeia*) as a suitable lotion for a moist dressing. Dr. GOUGH (Watford) considered splintage the primary treatment, and deprecated too early massage and movements. Mr. KENNON, replying, pointed out that evidence of decalcification of bone in the x-ray photograph of a septic hand should not be interpreted as osteomyelitis. He did not advise early massage, but was very much in favour of early active movements. He was in entire agreement as to the great advantages of having such cases treated as in-patients.

COMBINED SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND PUBLIC HEALTH

Wednesday, July 25th

RESULTS OF ANTE-NATAL CARE

The opening sessions of the Sections of Public Health and of Obstetrics and Gynaecology took the form of a combined meeting to discuss whether satisfaction could be felt with the results of ante-natal care. The obstetrical standpoint was presented by Dr. J. S. FAIRBAIRN and Professor F. J. BROWNE, and that of public health by Dr. ETHEL CASSIE (Birmingham) and Dr. G. F. BUCHAN (Willesden). These four papers are printed in full in the opening pages of this issue.

Professor J. M. MUNRO KERR (Glasgow), President of the Section of Obstetrics and Gynaecology, who was in the chair, welcomed the presence of the members of the Section of Public Health as a significant act of courtesy, indicating the promise of fruitful co-operation in the future as well as in the present. In Dr. Buchan's unavoidable absence, his paper was read by Dr. T. CARNWATH, President of the Section of Public Health.

Dr. E. H. T. NASH (M.O.H., Hounslow) said that public health administrators were in a difficult position, since general practitioners were losing their experience of midwifery, and it was doubtful how far their services would be utilizable in the future, as their knowledge of how to deal with emergencies was diminishing. Nevertheless, to take work away from them would be doing a disservice to the community. Much more co-operation was needed in the future between ante-natal clinics and practitioners.

Mr. ALECK BOURNE said that when ante-natal care was first instituted too much had been expected from it. Too many minor pathological conditions were being dealt with as though of major significance and requiring more serious treatment than was really necessary. Not enough consideration was being given to the management of labour without intervention, whenever possible. More confidence should be induced in the patient.

Dr. C. E. GAUTIER-SMITH (Bournemouth), speaking as a private general practitioner, regretted the insistence in the general press and in conversation upon obstetrical dangers. Many cases of primary inertia were of psychological origin. Parturition should be represented as an athletic feat, and ante-natal care be regulated accordingly. The capacity of the skull to mould was often forgotten. The private practitioner could do much to instil in the patient during ante-natal supervision that confidence which would ensure a happy issue. Dr. R. A. WELSH (Northumberland) asked how practitioners might hope to be remunerated for the work required of them in ante-natal supervision.

Dr. W. H. F. OXLEY (Poplar) referred to the coincident rise of maternal mortality and the increase in the number of ante-natal clinics, as shown by Dr. Cassie's figures. This might be attributed to the disappearance of the general practitioner in this connexion, and to the terror instilled in the prospective mother by the emphasis laid on maternal abnormalities. The importance of this

Aug. 4, 1934]

THE SECTIONS: SUMMARY OF PROCEEDINGS

THE BRITISH MEDICAL JOURNAL 221

psychological factor had not been stressed enough. Ante-natal work could not stop eclampsia, which might occur without previous albuminuria. Public health authorities should do more to get midwifery ante-natal work back into the hands of the general practitioner, who should have better access to hospital accommodation. Mr. L. C. RIVETT commended Dr. Oxley's system, with its stress on the work of the midwife, seconded by the general practitioner, and with the specialist in the background ready to help. Dr. JANE TURNBULL (Ministry of Health) said that the ante-natal clinic was an excellent co-ordinating agency, linking up local treatment with general subsidiary organizations. There could not be satisfaction with the results of ante-natal care in its present undeveloped state. Dr. W. P. GRIEVE (Ipswich) asked if eclampsia was always preventable. Dr. J. S. LOGAN (Swindon) said that while the number of births was increasing the demand for treatment was increasing. There was thus a loss of material for the purposes of training medical students and midwives. Dr. A. B. MURRAY (Banff) pointed out that conditions varied much in different parts of the country. Schemes too often began at the wrong end. The doctor should be in at the end. Even a good scheme was not universally applicable. Obstetrical specialists could not be utilized in widely scattered rural communities; the general practitioner was usually the vital factor, and should be the first concerned in consideration of schemes. But his training was usually inadequate, and his lack of experience was lamentable. Professor MUXRO KERR said that the stage of satisfactory with generalities had been passed. The establishment of normal pregnancy and labour, the creation of an obstetric conscience, the physical effect of pregnancy and labour, and other similar expressions were excellent catch-phrases for public addresses and good copy for the lay press, but the medical profession must get down to concrete proposals and well-defined details for improving the obstetric services of the country. The ante-natal service suitable for large urban areas, which must necessarily have a general-practitioner-midwife service, the best for rural and small urban areas, which must necessarily have a general-practitioner-midwife service. For densely populated industrial areas the only solution was the employment of midwives by local authorities. Properly paid and housed they should form an integral part of the local health service. Each midwife should be made responsible for the ante-natal care of 100 to 110 patients annually, operating from the local clinic and doing as much as possible of her work in it. The clinic would be open night and day, and house the obstetric outpatients as well as the clinical notes. Ancillary medical services should also be directed from the clinic, which should be in close liaison with the patient's health visitor. The midwife should be the patient's health visitor during pregnancy and the puerperium, as had been demonstrated by Dr. J. Buchan of Bradford, the only medical officer in this country. It had been very successful in Iceland and other Continental countries. Three other agents remained, less easy to adjust—namely, the midwife practising on her own account, the medical officer of the ante-natal clinic, and the local general practitioner. The midwife practising thus needed a large number of confinements to make a living, and could not adequately supervise her patients during pregnancy. She would have, therefore, to carry on her work in that part of the community which could pay higher fees, but would there be competing with the general practitioner. The clinic medical officer was too often inadequately trained, and under the present arrangement took no part in actual obstetric practice; the midwife, in cases of difficulty, summoned a general medical practitioner who might never have seen the patient before. The family medical practitioner would find it difficult to carry on the general required at a clinic, owing to the exigencies of general practice. He could only tie himself down to definite hours if there was established a general medical service for all insured persons and their dependants, and for all ailments. Such a service would operate from a general

welfare clinic, ante-natal work being then only a part of the general routine work of the medical practitioner. The speaker hoped that this solution would materialize. Medical practitioners would have to agree to conduct treatment of this kind in respect of insured persons in and from the clinics. Failing such agreement this line of medical work would be removed from the general practitioner as tuberculosis had been. In rural areas ante-natal work must be carried out by district nurses and general practitioners, for the clinic could not be utilized in sparsely populated districts. The results shown by the service of the village nurse-midwives of the Queen's Institute of District Nursing in England were wonderfully good, but there must be a greater supply of maternity beds localized in carefully selected towns. Dr. A. S. GARDEN (Southport) did not see how general practitioners could undertake ante-natal work. Dr. S. GORDON LUKER (Poole) entirely favoured doctors maintaining contact with ante-natal work and the subsequent confinements, but few had time to do so, or the keenness. The best results were obtained by keeping in touch with hospitals. Primigravidae were in their first pregnancies from multiparae. All women in their first pregnancies needed a medical adviser. Dr. T. G. STEVENS said that medical practitioners did not take the opportunities offered for examination. Teaching was not inadequate in the medical curriculum; any deficiency resulting was the fault of the medical students, who, as a class, were too often indifferent as regards obstetrics. Dr. FAIRBAIRN, replying, recalled a similar discussion at the Portsmouth meeting, which had been described as querulous. The general practitioner had done much to instruct teachers in obstetrics, and to instil confidence into patients. The study of the natural forces concerned was the important thing in ante-natal work, and the personal factor had to be definitely considered. The general practitioner was the ideal person to ensure natural physiological functioning before and during parturition. When he worked happily and closely with midwives the best results might be expected. The speaker referred to the Queen's Institute system, the figures of which indicated that the best results were obtained when preliminary work was carried out by the midwife, the doctor being called in secondarily when required. Dr. CARNWATH felt that preconception, or even ante-natal care was almost more important than ante-natal care. The best hope of progress lay in those agencies which were dealing with the health of growing girls, particularly in the years after leaving school. He thought that ante-natal clinics might have been better organized in the past, and there was more hope in the future of reducing the maternal mortality rate. Professor BROWNIE, in reply, agreed that very few cases of eclampsia could not be prevented, especially if our knowledge of the early signs of toxæmia was improved. Why should not the measurement of blood pressure become a routine? Dr. CASSIE said that ante-natal clinics had definitely reduced maternal morbidity.

SECTION OF PAEDIATRICS Wednesday, July 25th

With the President, Dr. F. JOHN POYNTON, in the chair, Dr. W. G. WYLLIE opened a discussion on encephalitis. He first classified the condition into suppurative and non-suppurative groups, and proceeded to review in particular the various types of the latter, dealing first with encephalitis lethargica and polio-encephalitis. After reviewing the clinical features of these varieties, Dr. Wyllie spoke at greater length on the group of encephalopathies associated with the acute fevers, exanthemata, and vaccination, all of which had been intensively studied in recent years. He described the family likeness of these forms of encephalitis, mentioning their abrupt appearance at least a week after the onset of the acute specific fever.

Meningeal symptoms and drowsiness occurred at the onset, leading to coma, and as the patient recovered consciousness various types of paralysis became obvious. Discussing the relative frequency of such complications of the exanthemata, Dr. WYLLIE drew attention to the raised incidence of recent years. Pathologically these forms of encephalitis fell into two groups—one with acute toxic changes and the other with demyelination. Finally, he gave an account of the type known as spontaneous acute disseminated encephalomyelitis. Here the condition arose spontaneously, but both clinically and pathologically it was again possible to recognize two varieties: one with toxic changes, with good eventual prognosis when the initial stages were safely over; the other, a demyelination type. In conclusion, he stressed the value of examination of the cerebro-spinal fluid, and briefly mentioned methods of treatment.

Dr. NEILL HOBHOUSE said that the impression he had got from personal experience was that encephalomyelitis secondary to exanthemata was remarkably rare, while the spontaneous form was extremely common. This was possibly because the relative benignity of the latter type allowed it to escape notice. He thought the diagnosis should be based not so much on symptoms as on the course of the disease. The characteristic points about this were the shifting of the symptoms, fresh ones developing when the earlier ones were clearing up, and that except in the comparatively few fatal cases the patients recovered completely without any lasting ill effects. Dr. Hobhouse spoke of the differential diagnosis, mentioning the two disorders for which acute encephalomyelitis was most likely to be mistaken. These were tuberculous meningitis and poliomyelitis, and in the former the most helpful point was the chloride content of the cerebro-spinal fluid, which was unaltered in the encephalitis cases. As regards poliomyelitis, he mentioned the fact that some active movements of apparently paralysed muscles could be obtained, even though the child was reluctant to move them, in the encephalitis as distinct from the infantile paralysis patients. Affection of the sphincters was common in the encephalomyelitis cases. In conclusion, Dr. Hobhouse spoke of acute hemiplegia, maintaining that this was more likely to be of vascular origin, and, this being venous rather than arterial, there were differences in behaviour from most cerebral vascular complications.

Dr. W. H. BEST (Bournemouth) dealt with the question of whether there were any controllable factors in cases of encephalitis which predisposed to infection, stressing the fact that specific treatment during the acute stage was futile at the present time. In the absence of precise knowledge it was necessary to fall back upon general prophylactic measures. He thought it of great importance that the mouth, nose, and throat should be kept as healthy as possible, and equally important was the thorough ventilation of class rooms and dormitories. Attention must be paid to the presence of vitamin A in the diet and the provision of pure, fresh milk for children. In addition, it was necessary to maintain a stable condition of the nervous system, eliminating as possible predisposing causes to encephalitis all forms of nervous exhaustion and emotional strain. Extra hours of sleep were also of value. Finally, Dr. Best mentioned the possibility of post-vaccinal encephalitis being related to a virus in the skin, and he stressed the importance of adequate measures to secure disinfection of the skin and of the instruments used.

Dr. T. R. HILL described his experience with children suffering from chronic or post-encephalitis lethargica. There were two broad groups: one with Parkinsonism and one with mental symptoms showing themselves as behaviour disorders. Although there were some mixed types, the fully developed cases tended to fall into one or other group. The symptoms of the behaviour disorder might appear during the acute attack, consisting of restlessness and wakefulness combined with impulsive and destructive. Dr. Hill discussed in detail the way in which the instincts and emotions in such cases appeared to have undergone exaggeration, emphasizing the fact that this was not due to loss of inhibition by the higher centres. He concluded by referring to the possibility that nervous or difficult children might suffer from constitu-

tional abnormalities of the same part of the nervous apparatus as was damaged in encephalitis lethargica. The PRESIDENT referred to cases of post-vaccinal and lethargic encephalitis which he had seen, and he mentioned the question of the relation of chorea to encephalitis. He regarded the former as a rheumatic meningo-encephalitis. Dr. G. M. FINDLAY spoke of viruses in relation to the central nervous system, dividing them into strictly neurotropic, those which can be rendered neurotropic, and non-neurotropic. He stressed the fact that no known virus by itself was capable of producing demyelination. Dr. H. CHODAK GREGORY asked for more information on prognosis. The parents of a child with encephalitis always wanted to know, first, if the child was going to recover, and, secondly, if the brain was going to be affected. Dr. B. E. SCHLESINGER mentioned the curious incubation period between the onset of the acute specific fever and the occurrence of encephalitis as a complication. He wondered whether allergy played a part in view of such a latent period. He asked, in conclusion, whether public bodies were not out of date in insisting upon vaccination before children could be admitted to convalescent homes. Antidiphtheritic inoculation seemed more logical at the present time. Dr. R. D. CLARKSON (Larbert) spoke of the similarity between chorea and some cases of lethargic encephalitis. He thought that a very long period was necessary after an attack of encephalitis before the final prognosis could be made with certainty.

SECTION OF NEUROLOGY, PSYCHOLOGICAL MEDICINE, AND MENTAL DISEASES

Wednesday, July 25th

THE USE OF NARCOTICS

With the President of the Section, Dr. LIONEL A. WEATHERLY (Bournemouth), in the chair, Lord HORDER opened a discussion on the use of narcotics in the treatment of nervous and mental patients.

Lord Horder distinguished between pain killers and sleep producers, although, he said, the two groups overlapped. The key to the successful treatment of insomnia was to find the cause or causes. These included psychological causes, especially anxiety (that is, mental pain) in various forms, and notably anxiety about not sleeping. They required psychological treatment. Most people, in fact, slept more than was necessary. Over-stimulation of the mind, over-fatigue of the body, dyspepsia, fever, circulatory and respiratory lesions, the psychoses—any or all of these might result in sleeplessness. As to remedies, all possible general measures should be considered first. The next approach was by way of drugs; alcohol and its derivatives as a hypnotic must be considered. Opium and its derivatives were indicated only where sleeplessness was due to severe pain. Hyoscine and the older hypnotics had long been used. The newer group—the barbiturates—marked a great advance because of exactness of dosage and constancy of effect. The ideal hypnotic unfortunately did not exist. It was not the drug, however, but the development of a drug habit that called for condemnation. Sedative drugs formed a means of escape from life. A definite scheme should be adopted for each patient. He was convinced that the ill effects attributed to hypnotics were considerably exaggerated.

Dr. R. CUNYNGHAM BROWN (Bournemouth) stated that in an inquiry instituted by the Board of Control it had been found that there was great variation in the kind and amount of sedatives used in mental hospitals. It seemed clear that the order and tranquillity of mental hospitals had little relation to the extent to which sedatives were employed. His own view was that for mental patients they played a valuable part in relieving feelings of anxiety and distress; in alleviating excitement; and in reducing violence. As pure hypnotics they were comparatively infrequently employed; insomnia *per se* seldom arose in mental hospitals or among psycho-

THE SECTIONS: SUMMARY OF PROCEEDINGS

AUG. 4, 1934]

Dr. JAMES COLLIER spoke of the actual effect of the barbiturates on the nervous system. These drugs, he said, tended to concentrate in the cerebro-spinal fluid, and thus acted specially upon the nervous system. Removal of cerebro-spinal fluid most effectively relieved cases of barbiturate poisoning. In some cases poisoning occurred without overdosage, probably due to abnormal retention: symptoms might suggest tumour of the quadrigeminal region. He considered the barbiturates safe and valuable drugs, and had not found any ill results from controlled medicinal administration. They might, however, be very dangerous where vitality was low and oxidation processes slow, and would therefore be absolutely contraindicated in pneumonia.

Dr. HAROLD SIMMONS (Bournemouth) said that from the point of view of general practice the relief of immediate symptoms was a preliminary necessity. Hypnotics were therefore often necessary as a first-aid measure. For nerve-racked patients he used bromide combined with some tasteless form of valerian, often replaced by small doses of luminal or chloralamide. Barbiturates, however, were usually needed to obtain sleep. The doctor's place as confidant often enabled great psychological help to be given by a general practitioner. In thirty-five years' experience he had never seen a case of habit from the use of barbiturates.

Dr. MARGARET VIVIAN (Bournemouth) stated that her experiences in her own nursing home for mental patients was that narcotics should be regarded as emergency measures and not as remedies likely to lead to cure. Of all forms of restraint drug restraint was the least desirable. Patients suffering from serious insomnia were never easy to deal with. Drug addicts suffering from withdrawal symptoms were also a very grave problem. Dr. Modinos in Egypt had treated such cases by auto-serotherapy: that is, he blistered the patient and re-injected the blister fluid. She had had a dramatic success with a doctor who was a morphine addict. This might also prove a valuable treatment for alcoholism. Dr. EDGAR MARTIN (Salisbury) thought that, although narcotics multiplied, sufferers from mental illness were increasing. It was not the drug that was to be considered but the use made of it. Each patient must be considered individually and the narcotics carefully chosen to suit individual needs. Dr. R. EAGER (Exminster) spoke of the lack of guidance in the use of narcotics which existed even to-day. Paraldehyde, for example, was given in some 90 per cent. of cases in mental hospitals in this country because it was regarded as safe and non-habit-forming. Its excretion through the lungs, however, made it a dangerous irritant of the mucous membrane. Attention to general health and to the way in which the day was spent by the wise use of occupation therapy, which was greatly encouraged in his own hospital, should go far to remove the necessity of narcotics for mental patients.

Sir ROBERT ARMSTRONG-JONES referred to the essential need for sleep, and stressed the danger of noise to the nervous system. Dr. T. A. WILLIAMS (Bordighera) mentioned Pavlov's definition of sleep as an inhibition. It was a form of escape from exhaustion. It was important otherwise would lead to exhaustion. It was important to remember this when dealing with cases of insomnia. He stressed the psychological factor, especially anxiety. He stressed the importance of a full inquiry into all the circumstances of the child's life. Psychological difficulties could not be cured by drugs alone. The results of the experiment he had carried out with Dr. Mary Barkas, at the Maudsley Hospital, on the treatment of dementia praecox by prolonged narcosis with somnifaine had been very disappointing. Dr. EDWARD MAPOTHER said that he had tried morphine on depressed and melancholic patients with unsatisfactory results. Somnifaine was useful on

account of its persistent effects, but it was of considerable danger when used to produce twilight sleep. Dr. DORIS ODLUM (Bournemouth) stressed the value of ammoniated tincture of valerian as an adjuvant to bromide, especially in the treatment of the psychoneuroses. She had found that the ordinary B.P. drug was more effective than the proprietary odourless preparations.

Lord HORDER, summing up, agreed that the adolescent was better for too much sleep rather than too little, but after the age of 20 over-sleeping was nothing but a bad habit, and represented an attempt to escape from the realities of life; it should be resisted strenuously. Daylight saving ought not to interfere with the sleep of children merely from the point of view of going to bed by daylight. Darkness should not be essential to sleep. In regard to Leduc's treatment by the galvanic current, he thought the effects might be largely attributed to suggestion, but if it succeeded in soothing the patient it was by no means to be despised on that account.

SECTION OF ANAESTHETICS Wednesday, July 25th

CLOSED ANAESTHESIA WITH CO₂ ABSORPTION
With Dr. C. F. HADFIELD, President of the Section, in the chair, Dr. W. B. PRIMROSE (Glasgow) opened a discussion on closed anaesthesia with CO₂ absorption. Dr. Primrose described a single-phase apparatus known as the anaesthetor M.7, in which expired carbon dioxide is absorbed by a solution of caustic soda and the essential feature of this system, he said, was the necessity for obtaining a gas-tight joint between the apparatus and the patient. This was effected by means of a pharyngeal tube carrying an inflatable rubber collar at its distal extremity. There was no necessity for proportioning the percentage of gases accurately, and oxygen was therefore supplied direct to the patient as his condition demanded. The apparatus was compact and light, easily handled, and simply constructed: there were no fine adjustments to become deranged. The working costs were the lowest possible, as the consumption of anaesthetic gas was independent of the duration of anaesthesia.

Dr. T. A. B. HARRIS gave an account of a two-phase apparatus in which carbon dioxide was absorbed by soda-lime incorporating a colour indicator. Anaesthetic gases were inspired from and expired into a bag fitted with a lever system, so that any predetermined pressure could be kept at a constant level. In this way the depth of anaesthesia could be automatically maintained. Dr. Harris believed that the absorption of carbon dioxide in a closed system of anaesthesia constituted a means of employing three physiological principles: (1) oxygen regulation based on the metabolic requirements of the patient; (2) the control of alveolar air; and (3) a regulating its partial pressure in alveolar air. He considered that the dead space should be as small as possible, and consequently he favoured a two-phase system. He considered that the dead space should be as small as possible, and consequently he favoured a two-phase system. He considered that the dead space should be as small as possible, and consequently he favoured a two-phase system.

Dr. FRANKIS EVANS, in an account of a two-phase apparatus designed as far as possible from standardized parts, said that soda-lime was employed in order to absorb carbon dioxide. He had found the proportion of this gas in the bag to be 0.45 per cent. after one hour, 1 per cent. after two hours, and 2 per cent. after three and a half hours' anaesthesia. Dr. Evans considered that, when using the single-tube method, the tube connecting the patient to the absorber should not exceed eight inches in length, otherwise the dead space constituted a decidedly adverse effect. In this respect he disagreed with Dr. Primrose. Apart from economy in use, carbon

AND BIOCHEMISTRY

Wednesday, July 25th

PATHOLOGY OF CORONARY OCCLUSION

With Professor JOHN S. YOUNG (Belfast), a vice-president, in the chair, Dr. R. T. GRANT opened a discussion on the pathology of occlusion of the coronary arteries.

Dr. Grant said that atheroma and thrombosis stood first as causes of coronary occlusion. The general factors in atheroma were advancing years and hypertension. It was difficult to say exactly how important hypertension was. In Levine's series 40 per cent. were known to have had hypertension and 4 per cent. were known not to have had it; no evidence was available in 56 per cent. Coarctation of the aorta caused hypertension from birth, and in each of three cases Lewis found atheroma and in one myocardial infarction. Abbott, however, in 200 cases did not record any such association. Animal experiments had given little help, and at present hypertension must be regarded merely as an intensifying factor in atheroma. The importance of diabetes had been established, though the mechanism was obscure. The significance of local factors in causation was suggested by the irregular distribution and favouring of certain sites. Necropsy findings did not support the view that the incidence of atheroma in the coronary arteries was exceptionally high. The incidence in the coronaries was highest about the origin of the anterior descending branch of the left coronary. There was little definite knowledge concerning thrombosis, but the chief factor was a diseased vessel. As a rule, the more severe the atheroma the greater was the risk of thrombosis, but there were many exceptions. If occlusion was slow, atrophy occurred and gradual fibrosis; if it was rapid, there was acute necrosis, also followed by fibrosis. It was difficult to offer any explanation but spasm for the occasional cases in which at necropsy no complete obstruction was found. A possible alternative was that, where the vessel was already narrowed, necrosis might be produced by reduction of blood supply from external causes, such as myocardial failure or reduction in blood pressure from haemorrhage. In rabbits acute anaemia combined with work on a treadmill could cause necrosis of the myocardium. Dr. Grant then discussed the cases of gradual coronary occlusion in which the myocardium survived. Here, he said, there must be an alternative supply. He explained the difficulties in accepting the view that thebesian vessels might nourish the myocardium, and suggested that more attention might be paid to the possibilities of other anastomotic channels, such as branches of the internal mammary and bronchial arteries and the vasa vasorum of aorta and pulmonary artery. Professor J. B. DUGUID (Cardiff) put forward the view that arterial degenerations tended to widen the arteries rather than to narrow them. He claimed that ordinary histological preparations did not give a true picture of the size of the artery in life. The wrinkling of the elastic lamina in histological sections supported this contention. It had been shown by Dr. C. V. Harrison that perfusion with sodium fluoride solution enabled one to study arteries in a more natural state. Professor Duguid showed slides of a perfused and an unperfused kidney from the same patient. The dilatation of an artery with each pulse wave was passive, and its contraction an elastic recoil; the latter failed in degenerate vessels. The elasticity and the post-mortem contraction of the vessel depended on the integrity of the media, while atheroma was a lesion of the intima. The evidence of any association between coronary atheroma and myocardial disease was slender.

Dr. GEOFFREY BOURNE recognized two main factors in the causation of coronary thrombosis—local disease and a tendency to thrombosis. Most cases of coronary atheroma never developed thrombosis, and therefore general factors must be important. He described two cases in which coronary thrombosis was associated with thrombosis of the retinal artery, and found two

dioxide absorption had the following advantages: no smell of ether in the theatre; rapid induction, recovery, and control; and extreme portability. The patient experienced less heat loss, and was guarded from bacterial infections of the respiratory tract. A well-fitting face-piece was preferable to a pharyngeal tube.

The PRESIDENT stated that experiments conducted some time ago showed that the amount of carbon monoxide present in nitrous oxide was negligible. He pleaded for care in the use of a Clausen harness. Dr. W. J. PHILLIPS (Newcastle-upon-Tyne) expressed a preference for endotracheal anaesthesia. He inquired if closed anaesthesia in conjunction with an endotracheal tube was feasible. Dr. BRENNAN (Manchester) thought that Dr. Primrose's pharyngeal tube showed no advantage over an endotracheal tube.

Dr. PRIMROSE, in reply, said that in his apparatus provision was made for lessening the dead space. The apparatus was expensive. As premedication he recommended the use of omnopon 1/3 grain without atropine or scopolamine. He had never had difficulty with the airway. Both Dr. Harris and Dr. Evans stated that they did not hesitate to use an endotracheal tube with this method of anaesthesia.

SODIUM EVIPAN

Dr. H. J. A. SIMMONS (Bournemouth), in a paper based on his experience of sodium evipan in 100 cases, said that one of the great advantages of this drug was the rapidity of induction; in the majority of cases amnesia was such that the patient remembered nothing after the insertion of the needle. The method employed was to inject the solution at a standardized rate with the patient counting; the total dose was double the amount given at the time the patient ceased to count, and in practice was nearly 10 c.cm. for an adult. He had observed that after induction with sodium evipan the amount of ether necessary to maintain relaxation was remarkably small. He had used this drug with success in obstetrical, dental, orthopaedic, and ophthalmic work; in the latter, the absence of vomiting was a great advantage. He had given sodium evipan in small doses with success in psychological cases which were resistant to suggestion. Regarding premedication, he was not impressed by the use of morphine or its derivatives in this connexion. In one case, after the subsequent administration of 7 c.cm. of sodium evipan solution to a young and healthy girl, it was necessary to give carbon dioxide and oxygen for over two hours, in addition to other stimulants, in order to resuscitate the patient.

The PRESIDENT did not advocate the use of sodium evipan in midwifery. Dr. EVANS thought the employment of morphine and its derivatives as a premedicament for sodium evipan was not without danger. He asked if Dr. Simmons had met with any cases of post-operative liver damage. Dr. R. K. FOULKES (Exeter) was of the opinion that premedications should be given with caution in all forms of basal anaesthesia. Dr. J. BECKETT (Dublin) regarded sodium evipan as uncertain in its action. For dental work he believed that this drug should not be administered to a patient in a dental chair. Dr. E. W. STRANGE (Wolverhampton) stated that he had used sodium evipan as an anaesthetic for thoracic surgery. Dr. BRENNAN (Manchester) had had no trouble with this drug. Dr. J. C. A. NORMAN (Broadstone) had given 7 c.cm. of the anaesthetic in midwifery, and had experienced no difficulty. Dr. O'DOWD (Birmingham) asked if there was a remedy for the excitement which was prone to follow the administration of sodium evipan. In his experience many cases were uncontrollable for some hours afterwards. Dr. FALKNER HILL (Manchester) believed that the drug should be employed with caution.

Dr. SIMMONS, in reply, said that he did not advocate the use of sodium evipan in the dental chair. He had found morphine useful for post-operative restlessness. He was convinced that the drug was a respiratory depressant.

Dr. RONALD JARMAN showed a film demonstrating the technique of administering sodium evipan.

THE SECTIONS: SUMMARY OF PROCEEDINGS

Aug. 4, 1934]

cases in the literature in which there was associated thrombosis elsewhere—in one instance a symptomless left subclavian thrombosis. The absence of symptoms in the last case suggested that the association might be found to be more frequent if it were searched for. Dr. Bourne pleaded for the discontinuance of the term angina pectoris, and for the classification of cases as coronary thrombosis, angina of effort, and spasmodic angina. The angina of the first had been determined. The angina of effort showed a constant relation between pain and effort which was probably due to the narrowing of the coronary artery. Post-mortem findings in such cases needed investigation. There appeared to be a further factor in spasmodic asthma. Two or three anginal attacks a day might occur for years, and these could not all be due to thromboses. A spasmodic theory was debatable, but could not at present be ruled out.

Dr. T. F. COTTON dealt with the pathological relations of pain, dyspnoea, and syncope in coronary occlusion. Pain was due to inadequate blood supply to the myocardium. The pain of sudden occlusion was characteristic; its severity bore no necessary relation to prognosis, which remained uncertain for three weeks. Many patients survived and became anginal subjects, and one-third of anginal cases gave a history of coronary occlusion. Anginal cases might have no serious consequences, or angina might follow years later. Prolonged pain was very suggestive of occlusion. Vaso-constriction was also a cause of pain. Functional vaso-constriction, which was a common give rise to ventricular fibrillation, which was a common cause of death in angina. Vaso-constriction and occlusion were distinguished by their response to nitroglycerin. Ischaemia from occlusion might cause any type of arrhythmia. Dr. Cotton described a case of auricular fibrillation following angina, in which an aneurysmal dilatation of the right auricle suggested that there had been obstruction of the blood supply to the pain, and that breathlessness often developed with the pain. Dyspnoea without pain was a symptom of heart failure. In some cases breathlessness had the features of asthma; there was pulmonary congestion without congestion of systemic veins, and the breathlessness was perhaps due to left ventricular failure. Syncope following occlusion might be difficult to distinguish from shock due to other causes, while biliary colic might be difficult to distinguish from coronary thrombosis. The syncope of the latter was from coronary thrombosis. Dr. A. S. STRACHAN (Johannesburg) described a case supporting Dr. Bourne's views in which at necropsy, in addition to the renal arteries, and thrombosis was found in the aorta, the renal arteries, and in practically every organ. In Johannesburg atheroma was found at a relatively early age, usually associated with calcification. The incidence of calcification of interest in view of the excess of sunshine and of calcium in the water in Johannesburg. The high incidence found among Jews suggested a dietary factor, and Dr. Strachan had found only two cases of coronary thrombosis in 2,000 native necropsies. Dr. W. N. LEAK (Winsford) inquired as to the possibility of anticipating the thrombosis, and as to the time relation of the pain and minutes of onset in a case seen within five minutes of the thrombosis. He described a case seen within five minutes of the thrombosis, which a cardiac stimulant appeared to have aborted an attack. Dr. S. S. SEZMAN described cases of coronary thrombosis with a history of previous attacks of temporary blindness from vascular spasm. This suggested that spasm might also be a factor in causing the myocardial infarction. Dr. H. McPHERDAN (Toronto) drew attention to cases of syncope without pain, proved to be due to coronary occlusion. He stressed the importance of the teeth—as a causal factor, and described a case of cholelithiasis simulating myocardial infarction.

Dr. GRANT, in reply, put forward some criticisms of Professor Duguid's theories. He maintained that there was much evidence to support the current view that the lumen of atheromatous vessels was narrowed. In reply to Dr. Leak, he expressed the view that the onset of cardiac pain meant that thrombosis was already complete.

PATHOLOGICAL BASIS OF SPLENIC ANAEMIA
Dr. J. McMICHAEL, in a paper on the pathological basis of splenic anaemia, said that out of ninety-six cases sixty-two fell into the category of hepato-lienal fibrosis. He showed a series of photomicrographs illustrating the development of siderotic nodules in this condition; the nodules were present in 46 per cent. of the cases.

SECTION OF RADIOLOGY AND ELECTROTHERAPEUTICS
Wednesday, July 25th

TREATMENT OF GENITO-URINARY DISEASES

Dr. W. J. TURRELL (Oxford) opened a discussion on electrotherapy in the treatment of diseases of the genito-urinary system, the President, Dr. DOUGLAS WEBSTER, being in the chair. Dr. Turrell's paper appeared in full in the *Journal* of July 28th (p. 160).

Dr. F. HOWARD HUMPHRIS, speaking on electrical treatment of the enlarged prostate, said that the increasing incidence of prostatic enlargement was the main reason why he pressed the claims of a method which had existed for thirty years. The static wave current acted mechanically, and stimulated the prostatic muscle. After describing the technique of the method, X-ray treatment, and the efficacy of the method, gave good results, and it was neglected in this country, that such treatment made subsequent prostatectomy more difficult. X-ray therapy was in his opinion untrue that such treatment, where there was much residual urine, and when cystitis or renal contraindications were present. Diathermy treatment was invaluable in prostatitis because it destroyed the organism *in situ*, and it should be continued until the secretion was sterile. It was not suggested that prostatectomy should be superseded by physiotherapy, but that a combination of these electrotherapeutic measures was adequate in many cases. Dr. D. D. MALPAS (Bournemouth) agreed that there was little evidence of increased difficulty in prostatectomy after X-ray treatment. Dr. AGNES SAVILL, speaking of pruritus and eczema vulvae, stressed the importance of the existence of discharge which might be due either to cervical, uterine, or tubal infection. Ionization should be employed for cervical and uterine infection, and diathermy for pelvic inflammation. Dr. Savill described the technique, and instanced several cases. Dr. G. B. BATTEN (Dulwich) contributed to the discussion, quoting the work of Dr. Justina Wilson on the destruction of organisms by diathermic means.

Dr. TURRELL, in reply, demonstrated the use of diathermy by means of diagrams of Leyden jars. Dr. A. J. DURDEN SMITH, in a paper on the use of radium in carcinoma of the bladder, referred to the divergent views held by urologists about radium treatment, and said that it should now be possible to come to definite conclusions as to its efficacy. It must be admitted that surgical results were not good, and that radium had a great deal to offer. After reviewing early methods of treatment, the advantages of radon seeds were discussed. The speaker described methods of interstitial radiation by the suprapubic route, and by the cystoscopic method, stressing the limitations in operable cases. Dr. Durden Smith referred to the use of radium in the inoperable group—results of excision in operable cases—and quoted which formed 60 per cent. of the cases—and quoted three-year results in a series of cases treated at the Radium Institute, London, and at other centres. The sequelae of radium treatment were sometimes, but not always severe. Experience showed that operable infiltrating growths should be excised, but that the use of radium was resulting in a large measure of success in the treatment of case, and especially in papillary carcinoma. Described a technique for treatment of epithelioma of the penis by surface application. The results in ten cases, after a period of nearly two years, showed that in nine cases the patients

were alive and well, and five of these after radium treatment alone. In carcinoma of the bladder he thought that adequate treatment by the suprapubic route at the Manchester Radium Institute were very encouraging. Dr. ROY WARD said that radium treatment in carcinoma of the penis was the method of choice in carefully selected cases. Either surface or interstitial radiation could be used, and retention of urine was a rare complication. In carcinoma of the prostate, interstitial irradiation was the method of choice, and palliative relief was considerable in a large proportion of cases. Dr. WARD quoted results in treatment in both diseases treated at the Radium Institute, London, since 1929. Dr. DURDEN SMITH, in connexion with Dr. HUTCHISON's paper, asked why subsequent amputation was necessary in four of his cases of carcinoma of the penis. Dr. HUTCHISON replied that two were recurrent after radium treatment, and two were in a condition of post-radiation necrosis. Mr. BERNARD WARD (Birmingham) confessed that he was disappointed that the radium treatment of carcinoma of the prostate did not give better results. He had himself used all methods of radium treatment, and had found none satisfactory.

Dr. DURDEN SMITH, in reply, agreed with Dr. Hutchison that the cytoscopic method of radium treatment of bladder cancer was not ideal, and that further advances would come by the employment of the suprapubic route. Dr. G. HARRISON ORTON read a paper on *x-ray treatment of the genito-urinary system*. He first defined the unit skin dose given by him—a dose which was 25 per cent. less than that used by many. He then described various *x-ray* therapeutic methods—the fractional dose, the single massive dose, the saturation method, and Coutard's technique. Of these the split dose was, in his opinion, the best in the largest number of cases. Most radiologists assumed that the hardest possible ray should be employed in treatment, but he doubted whether the quality of the ray was as important as the fact that a more uniform depth dose was possible. In malignant disease of the kidneys *x-ray* therapy sometimes made matters better temporarily in inoperable or recurrent cases. In bladder carcinoma the results were disappointing. Simple enlargement of the prostate was often improved by treatment in suitable cases. Malignant disease of the prostate was often alleviated temporarily, but relapse was usually early. Urinary infection might be aggravated by *x-ray* therapy. Testicular growths should be removed surgically, and *x-ray* therapy reserved for carcinoma of glands. Tuberculous epididymitis should be treated with doses of *x* rays. Dr. Harrison Orton thought that both radium and *x* rays should be employed in carcinoma of the cervix, *x* rays being preferable, given six weeks before radium. In carcinoma of the uterine body *x* rays were superior to radium, and remarkable results had been obtained in many ovarian growths. Describing the treatment of menorrhagia, the speaker said that, as a sterilization dose he gave 40 per cent. of the skin erythema dose to each ovary. In certain types of sterility and amenorrhoea small doses of *x* rays had proved successful in Hospital. Carcinoma of the vulva should be treated by radium, and *x-ray* treatment given to the inguinal glands.

Dr. S. L. MUCKLOW (Cheltenham) said that his experience of *x-ray* treatment of enlarged prostate was more favourable than that of Dr. Harrison Orton. He described in detail the technique used by himself and Dr. Curtis Webb, the results of which had been satisfactory in 80 per cent. of cases. *X-ray* therapy was indicated in all early cases and in those without much residual urine or marked intravesical enlargement. Dr. BATTEN said that he did not think that two or three ounces of residual urine was very important as a contraindication to treatment. The PRESIDENT, referring to Coutard's technique, said that Coutard had never seen late necrosis after the epidermicidal dose, and that this must be a matter of technique. He himself had employed the massive dose method once, but had then given it up on account of the

marked constitutional disturbance. There was still much to be discovered about radiation treatment. It was difficult to explain why, for instance, extensive skin deposits of breast carcinoma should disappear after small doses of *x* rays had been applied to the whole body. He was trying out Todd's method of intravenous sulphur and selenium followed by *x-ray* therapy, and it seemed that better results were being obtained than by radiation alone. In prostatic enlargement it was important to follow up all cases treated by *x* rays, and 90 per cent. of the full dose should be given to such cases. Dr. ORTON, in reply, said that he was interested in Coutard's assertion that less fibrosis was induced by his technique. As for the use of sulphur and selenium, many such substances had been employed during recent years, and he personally was not yet convinced of their value.

SECTION OF OTO-RHINO-LARYNGOLOGY Wednesday, July 25th

MUCO-PURULENT TUBO-TYMPANIC INFECTION
With Mr. J. S. FRASER (Edinburgh), the President, in the chair, Mr. RITCHIE RODGER (Hull) opened a discussion on muco-purulent tubo-tympanic infection.

Mr. Rodger said that the question whether a middle-ear infection would be confined to the anterior part of the tympanic cavity might depend on the causative germ. There were three types of mucosa in different parts of the middle ear, and it was well known that certain organisms showed a predilection for certain types of epithelium. The virulence of the organism, no matter what its type, might also determine whether the otitis media was going to be of the mild anterior or the severe posterior type. Again, the Eustachian tube itself might suffer so badly that it remained a source of serious infection. But, in his opinion, the chief causes of tubo-tympanic infection were to be found in the nasopharynx and its adnexa. Adenoids in children and sinus infection in adults were the most frequent contributing factors.

Mr. C. P. WILSON recognized two entirely different conditions—mucoid and muco-purulent. The former was associated with (a) a generalized catarrhal condition, and should be treated "generally"—that is, by dietetics, vitamins, and reduction of carbohydrates; and (b) a localized catarrhal hypertrophy necessitating local operative measures. The muco-purulent variety was associated with nasopharyngeal sepsis, antral or ethmoidal infection, or infection of air cells situated in the anterior end of the tympanic cavity, which necessitated various forms of conservative treatment or even a radical mastoid operation. Mr. E. B. WAGGETT confined his remarks to cases in the adult of chronic muco-purulent discharge in the absence of attic and mastoid infection. He did not agree with the opener that these cases were kept up by causes situated below the Eustachian tube. Marked and even complete nasal obstruction was commonly found without any aural catarrh. Concomitant acute infections of the sinuses and of the ear were frequent, and if neglected might go on to chronicity. Numberless cases of chronic sinusitis existed, however, without any middle-ear complication, although a pus stream could be detected in close proximity to the Eustachian tube. He advised intratympanic syringing, which brought away masses of opaque debris besides muco-pus. Mr. Waggett stated that it was the trypsin produced by the disintegration of the pus cells which destroyed the ciliated epithelium.

Sir JAMES DUNDAS-GRANT recommended in obstinate cases treatment through the Eustachian tube—for example, the inflation of a few drops of 1/2 or 1 per cent. chloride of zinc solution through the catheter, or, if the perforation was large, the injection of a weak Liel intratympanic tube until it dropped out of the meatus. The recognition of the essentially tubal origin of the chronic discharge and the appropriate treatment might save unnecessary mastoid operations. Mr. M. VLASTO considered the term "infection" as inappropriate. He

AUG. 4, 1934]

favoured the French view that the condition was a blennorrhoea of the Eustachian tube; and that inasmuch as the condition was an infirmity and not a disease, and was damaging neither to the life nor to the health of the patient, it could quite well be left to take care of itself. Mr. E. D. DAVIS recommended thorough cleansing of the tympanic cavity followed by dry treatment. Mr. HERBERT TILLEY agreed that chronic tubo-tympanic catarrh was a low-grade infection derived from the nasopharyngeal regions. The essential in treatment was free drainage through the Eustachian tube, and this might often be improved by the occasional passage of a fine Eustachian bougie. Mr. T. B. JOHNSON said that in his opinion the persistence of the catarrh in spite of treatment was due to infection of the Eustachian tube alone. He quoted A. McCALL (Bournemouth) drew attention to the importance of suction in treating this condition. He quoted cases where polypi had been sucked through the perforations and had subsequently healed. Dr. STEWART considered that the condition was usually due to some nasal abnormality; he disagreed with Mr. Waggett's conclusions.

FOCAL INFECTION AS A PROBLEM FOR THE LARYNGOLOGIST

Mr. A. J. M. WRIGHT (Bristol) opened the discussion on this subject with the paper printed in last week's *Journal* at page 158.

Mr. HERBERT TILLEY had come to the conclusion that the correct definition of a septic tonsil was that given by Professor Hajek—namely, that a chronic septic tonsil was one that was subject to frequent attacks of tonsillitis. The fact that secretion could be expressed from a tonsil was no indication for its removal. Professor H. S. BIRKETT (Montreal) said that he admired the surgeon who had the force of character to say "No" when the practitioner urged removal of a patient's tonsils. He thought it was the present position upon us. Mr. T. H. JUST stated that, in his opinion, many cases of acute nephritis or subacute otitis media. Mr. C. A. SCOTT RHOUD (Portsmouth) considered that some such definition as Mr. Tilley's of a septic tonsil seemed necessary, because work in hospital was becoming overburdened by the large number of cases for tonsillectomy sent up by the physicians.

SECTION OF OPHTHALMOLOGY

HEADACHES

With the President, Mr. LESLIE PATON, in the chair, Mr. A. D. GRIFFITH opened a discussion on headaches.

Speaking as an ophthalmologist, he said he found that 24 per cent. of his patients came to him for this symptom. In deciding whether a headache was of ocular origin the site and time of onset were of importance. Ocular headache was rarely temporal, and very seldom vertical, and only exceptionally did it develop other than towards the end of the day. Excessive accommodation was the usual mechanism for the production of error. Astigmatism, by inducing an unequal degree of contraction of the ciliary muscle, was another common factor. Whether illumination also played a part was an open question. Mr. Griffith held that, in attending to imbalance of the extraocular muscles, over-correction was a real pitfall. An uncommon source of headache was to be found in the occipital region from the pull on the occipital muscles through the frontales when patients habitually screwed up their eyes.

In the absence of Dr. Wilfred Harris the President summarized the contribution the former was to have made on the neurological aspect of the subject. Dr. HARRIS held that the conceptions that headache was due to a rise in intracranial pressure and that migraine was due

to irritation of the recurrent meningeal nerves were open to doubt, though there was considerable clinical evidence in favour of the former. Sudden rise in intracranial pressure, owing to a localized or generalized lesion, was certainly productive of headache. Migraine could best be explained as a consequence of spasm and subsequent throbbing and dilatation of the vessels of the occipital cortex, a view supported by ophthalmoscopic investigation of the retinal vessels. True migraine had some form or other of sensory prodromal symptoms. Speaking of ocular headache, he quoted recent work on inequality of retinal images as a factor. A variety of purely ocular lesions, as also cerebral arteriosclerosis, easily revealed by ophthalmoscopic changes, might give rise to headache. In conclusion, he pointed out that the condition he had named maxillary sinusitis required recognition, as treatment on physical lines was useless.

Dr. C. WORSTER-DROUGHT contributed a paper from the point of view of the general physician. He said that out of 158 cases referred to him for headache seventy-eight were of migraine. In sixteen cerebral arteriopathy or hyperpiasis without nephritis was present; in another sixteen no cause could be found; while the remaining cases were due to a variety of causes; cerebral tumour, eight; occipito-cervical fibrositis, six; gastro-intestinal disorders, four; effect of head injury, four; high myopia, three; diabetes, three; sinusitis, three; spontaneous sub-arachnoid haemorrhage, three; and other conditions. He doubted whether refractive errors were a factor in migraine. Speaking of cerebral arteriopathy he stressed the value of ophthalmoscopic examination, as general evidence might be lacking owing to the localization of the vascular lesion. The diagnosis of cerebral tumours was generally aided more by papilloedema than by headache. He considered that there was a characteristic type of headache associated with high myopia properly corrected. It was fronto-occipital in distribution, was present on waking in the morning, and got worse as the day advanced. Accessory sinus disease was not an important factor in his experience. Mr. MAURICE SORSBY, speaking as an oto-laryngologist, emphasized the significance of sinusitis. The presence of the sinuses greatly enlarged the area of irritation, transmitted along the fifth nerve. Sinus naked mucosa. In chronic affections this became an area of irritation, classified as originating from: (1) pressure, (2) vacuum, and (3) chronic irritation. The first headaches could be classified as originating from: (1) pressure, (2) vacuum, and (3) chronic irritation. The first was seen typically in the acute conditions, especially when the ostium became blocked. Toxic absorption was then also a factor. Vacuum headache was quite uncommon. Headache due to chronic irritation might sometimes be diagnosed by lipiodol radiography showing up thickened mucosa in sinuses otherwise negative. A pathognomonic type of headache was seen in frontal sinusitis. Most other types had no special features, except their presence on waking in the morning. In treatment, apart from radical operations, irrigation by the Proetz method and anaesthetizing the sphenopalatine ganglion should be considered. In conclusion, Mr. Sorsby pointed out that while in rhinology headache was a symptom, in otology it was a danger signal of intracranial complications.

The PRESIDENT drew attention to the diagnostic value of cocaine spray in cases of suspected vacuum headache. He held that the reason why such patients complained of eye symptoms, especially after reading, was that the downward movement of the globes in near work exerted a pull on the trochlea and so on the floor of the frontal sinus. Speaking of auto-intoxication headaches, he drew the analogy of toxæmia seen in the experimental condition of Eck's fistula; auto-intoxication headaches were typically supraorbital. He held that the suboccipital headache had an anatomical basis in the distribution of the nuclei of the fifth nerve, as he had shown a few years before. He asked for the opinion of the neurologists as to the mechanism of headache after lumbar puncture. In his experience a headache of particularly grave significance was that seen in people under 40, with hypertension and soft retinal exudates. Speaking of migraine from personal experience, he held that there was no true migraine except in which prodromal symptoms, and that vomiting was its work, associated with a special type. Mr. STENHOUSE

health classification and the

Dr. F. G. THOMSON, in the chair, Dr. Poulton opened a discussion on "The Relative Advantages of British and Foreign Health Resorts." Dr. Poulton classified health resorts into (1) spas, (2) resorts at the seaside, and (3) resorts inland. He emphasized the over-scepticism of the medical profession in matters of environment and climatic influences, both tangible and intangible, and their physiological effect on the human body, and quoted in support of this view certain interesting experiments carried out recently by Dr. Poulton enumerated the desiderata of these three types of resort, both from the medical and the social points of view, and stressed the importance of the British Health Resorts Association as a medium whereby the needs of the public might be correlated from both aspects. Reviewing known facts of the "tonic" climate and the "relaxing" type of climate, he referred to the experiments into the factors determining these, the exception of Bath all British spas belonged to the former category; this was of significance, he said, after treatment, he referred to the necessity for necessary substitution of the necessary factors.

...or "relaxing" "tonic" climate and the
Hill's experiments into the factors determining these. Reviewing
the former category; this was of significance in so far as
patients could, after treatment, return direct to their
work without the necessity for the "after-cure" period
generally necessary subsequent to a visit to a foreign spa.
The fact that England possessed no mountain climate
which was available medically was a legitimate indication
for treatment abroad. Dr. Poulton next spoke of the
place of sea bathing in medical treatment, and stated
that it would seem, as the result of certain researches,
at the seaside might vie with the mountains as a blood-
generating agent: further accurate investigations on
lthy subjects were needed. It was desirable, he con-
sidered, that any municipality intending to introduce
cal baths should put their plans before a medical
committee in order that sole control might not
nents, as was at present the case in certain resorts.
In conclusion, Dr. Poulton stressed the need for
the teaching of a non-obligatory nature in
climatology and medical hydrology.
at these subjects should be
of physical medicine should
to be given.

...the apt to be somewhat overlooked, owing to the
that Coates (Bath) continued the discussion
dermicid/INCENT reference to inland spas. He contrasted the

Dr. GEOFFREY HOLMES (Harrogate) stated that no central body in this country had sufficient funds to acquire the influence and importance of such bodies abroad. The pioneer efforts of the British Health Resorts Association as an unbiased medical body deserved the highest praise. The question of specialization depended upon two factors: (1) natural facilities, and (2) specialisation acquired by certain people in certain districts (e.g. of Nauheim). The general practitioner was in the position of a dilettante in the matter of specialisation with his patients, whereas the specialist was a dilettante in the matter of general practice.

The President invited discussion on health resorts.

Dr. HOLMES said, was

Dr. POULTON

Dr. COLLIS

Cox stated that the B. M. S. had present

Dr. VINCENT COATES thought it was a hand at all but first-class research for rest in rheumatic persons and by institutions. This was happening too frequently, merely for purposes of propaganda, both by Dr. E. P. POULTON, in reply, put the following of instruction to the meeting: "That regular be instituted in climatology and the University of Graduate Medicine granted."

The Ministry of Health has received the report of the county borough council on the subject of the proposed regular post-graduate courses in pathology and medical hydrology should be granted after examination." This was seconded by Dr. W. S. C. COPEMAN, and supported by several members present.

The Ministry of Health has forwarded to county and county borough councils in England and Wales copies of the report of a committee which was set up in 1931 by the Public Health Congress to explore the possibilities of the standardization of hospital equipment in this country. The more general aspects of the matter have also been dealt with in a report made by a committee on Standardization and Simplification of Requirements of Local Authorities, set up on the Minister's initiative by the Association of Local Authorities. This report will shortly be published through H.M. Stationery Office, and the Minister invites the attention of local authorities to the suggestions which it contains.

HEALTH VISITING IN AMERICA

HEALTH VISITING IN AMERICA

A NATIONAL SURVEY

Public health nursing in the United States took formal shape in 1912 with the coming into being of the national organization for that purpose. There are now in the U.S.A. some 5,000 agencies engaged in this work. They employ 20,000 nurses, as contrasted with 3,000 before 1912. Numerically, therefore, there has been a large expansion in the course of some twenty years. The expression "public health nursing" as used in America includes both morbidity and preventive services, or sick nursing and health visiting, as we should say in England. A survey of the present position has been carried out lately by the national organization with the aid of a grant from the Commonwealth Fund. Their report is now issued.¹

SCOPE OF THE REPORT

The field of investigation of the report is constituted by fifty-seven agencies in selected communities. Of these agencies twenty-one were voluntary nursing associations, eighteen were public health local authorities, and eighteen were local education authorities. Omitting the education authorities, which deal with a special group of the population, the services rendered by the voluntary associations and the local authorities are classified as: pre-natal care, post-partum care, infant supervision, pre-school child supervision, sick nursing, tuberculosis prevention, venereal disease prevention, infectious disease prevention, and conduct of labour. Of the voluntary associations 100 per cent. gave pre-natal care, 95 per cent. post-partum care, and sick nursing, and 52 per cent. infant supervision. Less than 50 per cent. provided the remaining services, but among these 38 per cent. undertook the conduct of labour. Of the local authorities 94 per cent. gave pre-natal care, 72 per cent. post-partum care, 83 per cent. infant supervision and pre-school child supervision, 61 per cent. tuberculosis prevention, 72 per cent. pre-natal care, and 61 per cent. post-partum care, venereal disease prevention, and infectious disease prevention. Twenty-eight per cent. offered sick nursing, but none undertook the conduct of labour. Considerable disparity is thus shown to exist in the commitments of the various agencies, and also, by comparison with this country, an apparent general narrowing of the fields of activity of local authorities.

PERSONNEL

Much of the substance of the report is concerned with questions relating to the quality of the nursing personnel—probably the most important single factor in determining the efficiency of any nursing service. All the ordinary nurses under the agencies regarding which information was obtained were registered State nurses, and only 25 per cent. had any experience of public health work before taking up duty. This means that in most cases a nurse entering the service of an agency itself. Where the agency possesses a staff qualified to teach, organizes adequate courses, and causes time to be made available for attendance upon them, the untrained nurses joining it may, by due diligence, reach an efficient standard. These conditions, however, do not appear to be fulfilled by most of the agencies. The arrangements made by them for teaching after appointment are described as "quite inadequate." The report notes further that the voluntary associations are meeting the problem better than the local health authorities or education authorities. It recognizes that such teaching after appointment must be the chief source of professional education for public health nursing in America, and one of its major recommendations is that every nursing agency should institute and maintain adequate educational courses.

¹ *Survey of Public Health Nursing: Administration and Practice*. By the National Organization for Public Health Nursing. New York: The Commonwealth Fund. London: H. Milford, Oxford University Press, 1934. (Pp. 282. 8s. 6d. net.)

NEED FOR CO-OPERATION

It is recommended also that nursing services should be at the disposal, not of the indigent only, but of the whole community, and to that end that it should be publicly announced in areas that the services are "available, at cost," to all who need them. It is urged, too, that every effort should be made to secure the good will and co-operation of the medical profession by establishing definite working relationships both with individual physicians and with organized medical groups. It is suggested that the voluntary agencies are focusing too narrowly on sick nursing, though some are creating members of the family health service for the conduct of labour the report recognizes that it is an expensive service and difficult to administer. Nevertheless, it ranks "high in importance," and the advice is given that all voluntary associations should assume responsibility for it, providing it either through a hospital or on a domiciliary basis. To the English reader it will appear remarkable that this advice is not extended, or even restricted, to the local health authorities, none of whom appear in the field of investigation as undertaking delivery care. Final pronouncements of the report are that the family must be the social unit for health work, and that each community should work out its own comprehensive policy with a view to a fully adapted health service, recognizing that of such a service public health nursing forms an integral part.

From the general sense of the report the view may perhaps be hazarded that public health nursing in the United States has, in some respects, advanced less far along the path of evolution than the corresponding services in this country, since questions which have been settled here seem there to be still open. In face of a document so outspoken and so obviously written for home edification it would be ungenerous to stress any discrepancies between American and English practice, which in any case owing to the differing conditions prevailing otherwise in the two countries may be more apparent than real. The report stands self-commended for the care with which its data have been secured and the competence with which they have been presented.

CHEMICAL RESEARCH AND INDUSTRY

In his recent presidential address to the Society of Chemical Industry Dr. J. T. Dunn spoke of the expansion of that industry during the past half-century. One of the influences which raised it from a comparatively lifeless state to the creative activity of to-day was the growth, hastened by the harsh experiences of the war, of the idea that the industry should be conducted by a chemist, or that the chemist should be consulted as to its conduct. "We learned something from the German chemical industry as to the importance of the chemist," he said, "and now we have realized that the chemical industry cannot be static; we must constantly be making investigations into the possibilities of improvements and developments." All the industries of this country were now staffed with chemists, whose business was not merely to check supplies and products and carry out routine testing, but to search out improvements in processes and new directions for advance. Perhaps the most striking feature of the change that had taken place was the importance that was now attached to research. Research workers should be given a free hand, and not forced to concentrate on commercial and industrial investigations only. Some of the most vital improvements in industrial progress had been due to discoveries made in the first instance by men who were simply under the urge of inquiry into the working of nature, with no industrial end in view. It behoved those who conducted industry not to confine themselves to the straight path of "directed" research, but to encourage "fundamental" research by those of their staff who had a flair for it. It might not yield anything for a time, but at any moment it might bring forth fruit of all directions. The chemical industry had branched out in all directions so that there was hardly any aspect of daily life in which people did not come into contact with the chemist.

Increased Mortality from Diabetes

SIR.—The article published in the *Journal* of July 28th (p. 175) under the above heading is likely to set many speculating on the cause or causes of the increase in question. We are told that

"diabetic mortality is increasing all over the civilized world. In the United States registration area it has advanced from twenty-seventh in rank in 1900 to ninth in 1932. In practically every European country there is a comparable increase, and countries of European descent, like New Zealand and Australia, share in it. . . . In England the recent death rates are the highest on record, that of 1931 being 29.5 per cent. higher than in 1925 and 45 per cent. higher than in 1920."

How are we to account for this widespread increase in diabetic mortality? Two outstanding causes at once suggest themselves: (1) the increased consumption of concentrated sugar, and (2) the increased "rush," stress, and strain of modern life.

It is, I believe, generally agreed that excessive indulgence in concentrated sugar, by exhausting the cells which secrete insulin, tends to engender diabetes (sugar, curiously enough, being in this respect more potent than starch). Now, with the significant exception of the temporary fall in sugar consumption and diabetic mortality consequent of the World War, the yearly consumption of sugar in America and in many European countries has tended to rise during the present century.

Statistics show that, while a placid, unexciting life is associated with a low diabetic death rate, a life of excitement and strain has the opposite effect: "The labourer and the manual worker have the lowest death rate; that of the professional man and the mental worker is much higher." Now excitement and nerve strain have enormously increased within recent years owing to the introduction of the motor vehicle, the cinema, the wireless, and the aeroplane, to say nothing of the telephone and the gramophone.

These two factors, then—the increased consumption of sugar and the increasing tension of modern life—seem well calculated to aggravate a diabetic tendency. As to the age factor, it is significant that the increase of diabetic mortality is limited to the later decades of life. Below the age of 45 the death rate among diabetics "has actually declined." Indeed, in young subjects it has fallen more than half. No doubt this lowered death rate in early life is the result of insulin treatment. It is not surprising that, since the introduction of insulin, the death rate should have risen considerably among the elderly and aged: insulin does not actually cure the disease diabetes; it facilitates the assimilation of sugar and enables a large number of diabetics to survive the age of 45, and thus increases the diabetic mortality thereafter. The recent phenomenal change in the sex mortality of diabetes presents a difficult problem. It seems that "some twenty years ago more men died from diabetes than women, and the death rate in males has risen very little. In women under 35 there is also no recent increase, but in later life a very substantial rise has taken place, until at the age of 65 the number of female deaths is twice that of males."

What has happened in the lives of women to account for this anomaly? Women nowadays lead more vivid and exciting lives than formerly, they bear fewer children, and they often smoke immoderately; but I do not know that any of these innovations throw much light on the dermic question.—I am, etc.,

method on, W. 1, July 29th.

HARRY CAMPBELL.

The Swab in Diphtheria Diagnosis

SIR.—How much longer is the swab to be relied upon in the diagnosis of faucial diphtheria? It is surely common knowledge that negative cultures are often obtained in severe and fatal cases, and there must be room for improvement in a method of diagnosis which may result in one patient being admitted to hospital in a moribund condition, while the next unfortunate, with a clean or slightly inflamed throat, is labelled "diphtheria".

Of the last forty fatal cases of diphtheria admitted here, twenty-four were sent in on purely clinical evidence. Of the other sixteen, the swab was positive in four and negative in twelve. I suggest that in every doubtful case either (1) the opinion should be obtained of someone familiar with the diphtheritic throat, or (2) the patient should be sent to hospital for observation. If neither course is possible, a swab may be taken provided that not less than 20,000 units of diphtheria antitoxin are given intramuscularly at the same time.

If the policy of swabbing every sore throat were abandoned in favour of one such as I have indicated, the gain would be infinitely greater than the loss.—I am, etc.,

Isolation Hospital, Romford, July 26th.

E. JAMES.

Syphilis and "Cure"

SIR.—Dr. Henry MacCormac's paper (*Journal*, July 21st, p. 99) raises, I think, a most important and always present question—the meaning of the word "cured" as applied to syphilis, especially with regard to patients who are discovered to have syphilis at a V.D. clinic, are warned as to the terrible disease that they are possessed of, and are more or less definitely promised that if they are good and continue treatment for two years they will be "cured."

Dr. MacCormac tells us that early syphilis is curable, and he informs us that he is using the word "cure" in its literal sense, and this because we possess specific remedies and a specific test. From this he goes on, I think, to prove very ably that early syphilis is not curable, and that the "specific" test is not specific. With regard to the Wassermann reaction, is it not a test for the presence in the body of a reaction against the specific disease syphilis, or other diseases giving this reaction, rather than a test for those specific diseases? This is not merely putting the same thing the other way round. It puts the syphilitic patient with a negative Wassermann into line with any patient suffering from some specific disease with the body so enfeebled that it is putting up no resistance against it.

Dr. MacCormac goes on to quote a case of relapse (No. 1163) which had had two full years of treatment and a persistently negative Wassermann; he says that this, of course, merely a discrepancy such that one might expect to meet. We note, however, that this is merely in confidence ten, twenty, and even thirty years for the development of tabes and other late manifestations among the "cured" patients?

I have at hand the notes of a patient who presented himself at a London clinic with a secondary rash nine years ago. He received treatment for two full years, and I am told attended most religiously. His blood and cerebro-spinal fluid both showed a negative Wassermann, and this has remained negative ever since. Even now the Wassermann in both his blood and cerebro-spinal fluid is negative, but in spite of this he now presents definite signs of tabes dorsalis, and I am sure that cases of this kind are not at all uncommon. I think from all this that our outlook on patients who have had syphilis,

and have been treated, and have a negative Wassermann reaction, should be somewhat as follows. These patients fall into two groups: Group I, who have had the disease eradicated; and Group II, those who, though they have the disease lurking somewhere in their systems (it may be merely a few odd spirochaetes hiding somewhere in an aortic cusp, or in the neighbourhood of a posterior nerve root), are incapable of putting up any fight against the disease. That Group II exists, and forms a considerable proportion of the "cured" cases, cannot be doubted. As to the relative size of Group I, assuming that it exists, I think that we must yet wait many years for such a fact to become established.—I am, etc.,

Gateshead, July 23rd.

M. CHALK, M.R.C.S.

Asthma and Chronic Bronchitis

SIR,—Dr. Christopherson, in the *Journal* of July 21st (p. 139), ascribes to me the theory that asthma and chronic bronchitis are due to thyroid deficiency. I did not intend to suggest that this was the case, any more than he himself would attribute asthma to sodium iodide deficiency.

I should rather say that the sympathetic system, including the thyroid and suprarenal glands, fails to react to normally effective stimuli, not so much because of any inherent defect, but because the reflex paths concerned have not developed and "facilitation" has not occurred. The child who is unduly protected from his environment will not acquire an "emergency reaction" capable of clearing his bronchi. He is being asked to run before he has been allowed to walk.

I agree with his conception of chronic bronchitis and asthma as a manifestation of autonomic incoordination rather than a result of local bacterial action. Whether the actual "cause" of the asthma is "vagus spasm" or sympathetic defect is less certain, but some common findings in asthmatics support the latter hypothesis. The subnormal metabolic rate, low blood sugar, and low blood pressure point to abnormally low sympathetic tone.

It is known that certain acute infections—for example, influenza, measles, whooping-cough, and diphtheria—tend to be followed by a similar syndrome, and may be starting-points for asthma. What is not so commonly realized is that autonomic balance is the normal method of temperature regulation, and that undue restriction of heat loss by excessive clothing and indoor habits, or even by poulticing or steam inhalations, must tend either to sympathetic inhibition or to pyrexia. In the former case bronchospasm is likely to develop. We know in practice that the so-called allergic diseases tend to occur chiefly in the summer months. The obvious exception of winter bronchitis is accounted for by over-clothing and overheated rooms, combined with indoor habits.

In conclusion, I should like to refer to Sir Leonard Hill's paper in the *Journal* of June 24th, 1933 (p. 1096), in which he points out the connexion between overheating and nasal congestion, which is so often the precursor of more serious respiratory diseases.—I am, etc.,

Bradford, July 23rd.

H. S. RUSSELL, M.D.

Asthma in Children

SIR,—In view of recent correspondence on the above subject, I venture to claim consideration for treatment of such nasal abnormalities as may be present. Although this is only one element in the production of asthma it is a very important one, and should not be left out of account in any obstinate case. In a communication on "Asthma in Children Relieved by Intranasal Operation," published in the *Lancet* (February 28th, 1931, p. 468), will be found short notes of a series of cases of operative

treatment for intranasal conditions (chiefly enlargement of the middle turbinate body) in children suffering from spasmodic asthma. They were eighteen in number, and in only two was there failure to obtain relief at the time, while even in these freedom from asthma was reported later on. The difficulties inherent in such operations in children and the methods of dealing with them are there discussed.—I am, etc.,

London, N.W.1, July 30th.

JAMES DUNDAS-GRANT.

Non-specific Colitis

SIR,—Dr. Dorothy Hare's paper, though interesting, is not very convincing from a practical point of view. Quite recently I treated two cases of severe long-standing colitis with parathyroid and calcium tablets, taka-diastase after meals, and big doses of kaolin with astringents. At the same time carbohydrates were cut off, and the patients encouraged to eat more fleshy food. Both recovered rapidly. Colonic irrigation is of no earthly use.—I am, etc.,

Wigan, July 30th.

J. THOMSON SHIRLAW.

Occupational Therapy

SIR,—I was interested to read your report of the recent conference in London regarding this method in the treatment of psychical illness. The following sentences from that report ought to be read and re-read. Dr. Elizabeth Casson

"was convinced of the immense therapeutic value of the time-table of exercise, occupation, amusement, and rest in the treatment both of the psychoses and of the psychoneuroses. Nothing was worse for patients than to drift about aimlessly. The carrying out of such a regime required the loyal co-operation of every member of the staff."

And Miss Ruth Darwin of the Board of Control stated:

"Occupation to be really successful must not be confined to a special room or an hour two or three times a week, but carried on daily in the wards. It appeared to be a psychological necessity for all humanity, whether mentally sick or mentally sound, to have some occupation with an object."

Let me re-state this. Each patient ought to have a time-table or programme, carefully drawn up and individualized, as also susceptible of modification whenever necessary; stereotyped programmes, "the same for all," are useless, and often worse than useless. Aimless drifting about is pernicious. It is a "psychological necessity" for everybody to have a job. Occupation is not a secondary matter; it is the primary need of the individual's life. Finally, in a hospital, the whole staff must co-operate with whoever is in charge of the patient, whether he calls himself doctor or merely "occupational specialist." How true all this is, and how very much in accord with experience! One is, however, a little surprised to read the statement by the chairman, Sir Henry Gauvain, that occupation therapy is a movement "of recent development." Surely one doesn't need to be a psychological specialist to know that people tend to become nervously and even mentally unstable when they have nothing to do, and that they become quickly better when they find an intelligent job, suited to their special aptitudes; nor was this observation made yesterday! But possibly the chairman was referring to the "scientific" utilization of such common-sense methods by medical men. He may be right regarding the official hospitals, but it is only fair to say that quite a number of practitioners specializing in the treatment of neurasthenia and the like have been insisting on the value of occupational therapy since even pre-war days.

If a personal note may be allowed, I should like to say that I advocated similar methods in two letters to the

British Medical Journal in 1910 (June 18th and July 16th), elaborating my thesis still further in an article contributed to the *Edinburgh Medical Journal* in May, 1911 ("Ergotherapy in Neurasthenia"). Prolonged experience since then, including treatment of a large series of shell-shock cases during the war, has done nothing but strengthen me in the belief that occupation therapy is the treatment *par excellence* in at least the milder psychoses or psychoneuroses. Even the alienists, with their more inveterate cases, are apparently able to make considerable use of this method.

As with all good things, however, there is, I think, a danger of this therapy becoming over-systematized and hypercharged with verbalisms.—I am, etc.,
ARTHUR J. BROCK, M.D.

Garth Hill House, North Queensferry,
Fife, July 25th.

Thrombosis of Internal Saphenous Vein

SIR,—Dr. Stanley Parkinson's letter in the *Journal* of July 28th (p. 183) is one which will, in my opinion, cause unnecessary operations and alarm. I have always contended that superficial phlebitis, whether in varicose or normal veins, should not be treated by rest in bed or any ligation operation. The effect of rest in bed, with the patient in a "thrombosing frame of mind," will be to produce deep thrombosis in the tibial, femoral, or iliac veins, with clots large enough to cause a fatal or severe embolism. Surely Dr. Parkinson cannot imagine that a clot the size of a split-pea in the internal saphenous could cause a fatal embolism. The patient's death was probably due to massive embolism following thrombosis of iliac veins after three months in bed, or a coronary thrombus.

The rational treatment for superficial phlebitis of the legs is a firm compression bandage of elastoplast from the toes up to the level of the clot, with a firm pad of sponge rubber at this point to prevent the clot from moving. The patient is kept fully ambulant, and pain, induration, and temperature all disappear like magic, and no extension of the phlebitis occurs. I have treated a very large series of cases in this way, and there were no lethal gurgles at midnight or necessity for cardiac massage in any case, and not one patient has ever asked to go back to the old six to twelve weeks in bed.

As to ligation of superficial vessels for thrombosis, I need only say that I frequently do this operation to produce thrombosis in cases which do not respond to injections alone, and find it a very certain method of inducing thrombosis, especially *above* the ligature.—I am, etc.,

London, W.1, July 28th

A. DICKSON WRIGHT.

Inflammatory Dislocation of the Atlas

SIR,—I have read with much interest and instruction the paper by Mr. Duncan C. L. Fitzwilliams on "Inflammatory Dislocation of the Atlas," in your issue of July 21st (p. 107). In it he refers to a case which Dr. P. F. Frazer and I recorded in the *Lancet* in November last, but says of it that it "was an excellent example of tuberculous caries in a man of 30." The case we recorded was quite definitely, not tuberculous, and a reference to the full history given and to the radiographs by Dr. Harold Black will, I think, convince anyone on this point. Our case differs in a number of features from his two. Ours was a complete forward dislocation of the atlas, the anterior arch being markedly separated from the upstanding odontoid process, and the head remaining in the midline with the chin resting on the sternum: in both his cases there was a subluxation on the left side only, the first being associated with rheumatic pains in several joints, including the shoulders, and the second being associated with

septic glands of the neck, mainly left-sided, and a quinsy (side not stated). Like his, our case was essentially spontaneous, but, unlike any that we could find in the literature, was entirely apyrexial.

I am familiar with the unilateral subluxation between atlas and axis occurring in children with torticollis associated with cervical adenitis, x-ray pictures sometimes revealing a most disquieting and wholly unsuspected state of affairs. Through the kindness of Mr. Robert Milne I am also familiar with the subluxation, either unilateral or bilateral, occurring in children during acute rheumatism. But in none of these was there such complete bilateral dislocation, marked separation of odontoid process from the anterior arch of the atlas, or neurological evidence of the medulla being kinked over the odontoid peg by the forwardly displaced head, as our case exhibited. For these reasons I think the pathological processes at work in the complete forward dislocation must be different from those in unilateral subluxation, and while Grieg's hypothesis of ligamentous softening as a result of decalcification of hypervascular bone may explain these latter, I am concerned. Wittek's theory so far as the former are concerned. Wittek suggested that the bursa between the anterior arch of the atlas and the odontoid peg, and also that between the odontoid peg and the transverse ligament, became inflamed, and therefore distended, this distension stretching the ligament, and thereby allowing a complete forward dislocation. He refers to the condition as "dislocation luxation" of the atlas, and it appears to us as the right explanation.—I am, etc.,
Birmingham, July 25th.

F. A. R. STAMMERS.

Peripheral Neuritis Complicating Measles

SIR,—Dr. Urquhart, in the report of his case of measles and peripheral neuritis, published in the *Journal* of July 21st, states that he has been "unable to find in a fairly exhaustive literature any but a passing reference to the occurrence of multiple peripheral neuritis as a complication of this fever."

The occurrence was recognized last century: Morton,¹ writing in 1897, left a good account of it. From Allyn's² description it seems likely that the case described by Liégard³ in 1859 was another of this type. Greenbaum,⁴ in 1907, was able to find eight cases; of his series of 138 cases of non-diphtheritic multiple neuritis in children more followed measles than any other infectious fever. Nevertheless, it is an even more uncommon complication than is encephalitis. It seems probable that the following was a mild case of this kind.

A girl, aged 3 years, contracted measles in April, 1934, the rash appearing on the 20th of the month. She was in bed ten days; on the eleventh and twelfth days she walked a little in the bedroom. On the thirteenth day she got up again, and "fainted," her legs collapsing beneath her. She was put back to bed; she seemed unhappy, and had lost her appetite.

On the twenty-fourth day she was admitted to the Hospital for Sick Children, Great Ormond Street. On examination she was found to be fretful; she resented being touched, especially on the legs. She could speak intelligently, and was not drowsy. She would not sit up, and complained of pain if one attempted to move her into a sitting posture. There seemed to be some weakness of the neck muscles, but no obvious loss of power elsewhere, though she was averse to moving her legs. She had a left facial palsy, involving the orbicularis palpebrarum. Her pupillary reflexes were normal, superficial abdominal weak but equal, plantar flexor; biceps, triceps, and knee jerks could not be obtained. The fundi were normal; there was no definite muscle tenderness; sensation was difficult to test, but there was no obvious loss.

¹ Morton: *Arch. Paediat.*, 1897, xiv, 541.
² Allyn, H. B.: *Med. News*, 1891, lix, 617.
³ Liégard: *Gaz. des Hôp.*, 1859, 562.
⁴ Thomas, H. M., and Greenbaum, H. S.: *Journ. Amer. Med. Assoc.*, 1907, xlviii, 1397.

Nothing abnormal was found on examination of her chest and abdomen; her tonsils were large. The cerebro-spinal fluid was under normal pressure; it contained less than five cells per cubic millimetre, 0.07 per cent. albumin, 0.72 per cent. chlorides. The blood Wassermann reaction was negative.

On the thirty-fourth day she still could not sit up; she resented attempts to extend her knees, but four days later she was able to sit up and to smile, her facial palsy had almost disappeared, and her knee-jerks were still absent. On the sixty-second day she walked a little; her knee-jerks were still absent. Unfortunately she developed whooping-cough at this time and was sent home. She is now at the seaside, and her mother, ninety days after the onset of the rash, reports that the child can walk easily and seems very well.

I am grateful to Dr. Thursfield for allowing me to describe this case, which was in his care in hospital.—I am, etc.,

Hospital for Sick Children, Great Ormond Street, July 23rd.

P. R. EVANS.

Maternal Mortality in Maoris

SIR,—With regard to Dr. T. L. Paget's remark in the *Journal* of April 7th (p. 644) that the late Mr. Elsdon Best's statement concerning maternal mortality among the Maoris was obtained from a too limited knowledge of obstetric conditions, and was probably based on conclusions drawn from one or two easy cases of labour with which he was acquainted, it may be well to mention that Mr. Best obtained most of his information from the Maoris of the Tuhoe tribe. Because the Maori was intelligent, had an excellent memory, and was very anxious to preserve his tribal records, racial myths, and traditions, this information is of more value than it would be in the case of a race without these attributes. As an instance of their good memory, a case is given of an old Maori man who recited the genealogy of his sub-tribe for many generations, which necessitated the memorizing of 1,400 names. In cases of difficult childbirth, which sometimes did occur, a woman would get her husband to "wananga" her ancestral descent—that is, to repeat her ancestral descent from the period of Darkness, the beginning of things, down to herself.

The following sentences are taken from Mr. Best's work *The Maori*, and from his articles in the *Journal of the Polynesian Society*.

"All these natives concur in saying that formerly women were very seldom ill during or after parturition." "If a woman dies in giving birth to a child, an almost unknown occurrence, the child is given to a woman in milk to suckle and tend." "The following remarks were sent to me by Hori Rapaha of Waipawa in 1893, in a written communication: 'Women of the Maori folk did not die in childbirth [formerly]; although a native woman might give birth to many children, yet she would not in any case die. Maori women were of a fine type, robust and healthy, and wise in matters pertaining to childbirth, they did not succumb. In these times many native women die [in childbirth]; the women who so die in a single year may perchance amount to a hundred, or even as much as two hundred.'" (This remark is of interest.) "Some very singular traditions are retained by the Maoris in regard to the Caesarean operation having been performed in former times, but such are always located in some far-distant land, inhabited by primitive people, who are often unacquainted with fire, or if localized are relegated to times long passed away."

With regard to the teeth, the following may be quoted:

"Dr. Scott also notes the fact that the teeth in skulls examined by him had the whole crowns ground away, but that he never detected any signs of dental caries. The present writer has noted the same peculiarity in many old native skulls seen in caves and hollow trees, where they had been deposited after the exhumation of the tribal dead." "Judging from the teeth seen in many hundreds of old skulls, the Maori should not have suffered much from tooth-ache in olden times."

The same authority states that he has observed that the older natives are by far the most robust, much more so than the younger people and children, and also that the natives of the Tuhoe tribe say that their women have more trouble in menstruation than they had formerly, difficult and painful menstruation being very rare in former times, a fact which Mr. Best thought might be connected with the increasing lack of fecundity so noticeable among these tribes.

As to the custom of squatting instead of using seats, a Maori guide at Whakarewarewa, Rotorua, recently stated that squatting was common only among the old people. This was certainly true of a near-by group, the elderly grey-haired women squatting on the ground, while the younger people were seated. However, this relates to the habits of a comparatively few Maoris on the outskirts of a town, and may not be true of the race as a whole. With only our present-day conditions to judge from, it is difficult to imagine that there may have been, at some time, races in which childbirth was a normal process. For it is difficult not to agree with what Joseph DeLee writes in the introduction to his work on obstetrics.

"Is labour in the woman of to-day a normal function? I say it should be, but it is not. Can a function so perilous, that in spite of the best care it kills thousands of women every year, that leaves a quarter of the women more or less invalided, and the majority with permanent anatomic changes of structure, that is always attended by severe pain and tearing of tissues, and that kills 3 to 5 per cent. of children—can such a function be called normal?"

—I am, etc.,

Auckland, New Zealand, June 5th. VIOLET E. HASTINGS.

Use of "Oil" Vaccine in Rheumatism

SIR,—In the vaccine treatment of chronic rheumatic diseases, as in asthma, certain cases develop a degree of sensitiveness which may render them almost uninoculable. The causation of this hypersensitivity is unknown, but it seemed possible that if the absorption of the vaccine could be slowed down the effect of a dose might then be less drastic. The idea followed from the well-known fact that a protein molecule when adsorbed on to a colloid particle and injected into the body exerts its effect on the tissues less readily than when given in a simple solution.

The recent work of Walsh and Fraser and of Myers, where the lethal effect of tetanus and diphtheria toxin was greatly lessened by adsorption on to various colloids, is a striking example of this phenomenon. It was a simple matter to mix vaccine with a dilute emulsion of olive oil rendered isotonic by the addition of mannitol, and thirty-six cases have now been treated with adsorbed vaccine at the Charterhouse Rheumatism Clinic. (The emulsion of olive oil of a strength of 3.8 per cent. (Walsh and Fraser) was prepared for me by British Colloids, Ltd., whose help has been most valuable.) The trial has extended over two months, during which 150 doses have been given (average per patient 4.16).

A number of these patients, who seemed to be at a complete standstill, have again started to improve on the "oil" vaccine. The difference between the effect of this and ordinary vaccine is very striking. Thus the average sub-reaction dose of ordinary vaccine worked out at 4,500 streptococci and staphylococci in equal numbers, the "oil" at 169,000. That is to say that, on the average, the oil-adsorbed vaccine is 37.5 times less "toxic" than the ordinary. In practice it has been found that ten times the reaction dose is usually well tolerated, and followed by improvement in focal symptoms with a sense of well-being. By way of test, proportionately much larger doses have been given, but these have occasionally provoked nasty reactions, and in

any case the aim of treatment is not to give the largest possible dose, but that sub-reactional dose which is followed by the longest period of improvement. Experiments are now being carried out to determine the best and most stable colloid for the purpose. The above results also suggest the possibility of obtaining a high degree of immunity from the use of adsorbed prophylactic vaccine without the risk of unpleasant reactions.—I am, etc.,
London, W.1, July 23rd.

H. WARREN CROWE.

Vitamin A Deficiency

SIR,—In an interesting article published in the *Journal* of July 21st (p. 113), bearing the title "A Cutaneous Manifestation of Vitamin A Deficiency," Dr. G. P. Goodwin says that until about a year ago the occurrence of vitamin A deficiency in man had only been diagnosed with certainty when eye changes had been found, and he appears to be supported in this supposition by Dr. Helen M. M. Mackay, who writes a note to his paper.

In 1927 I described a deficiency disease which I denominated the A and B avitaminosis disease of Sierra Leone, and the paper was published in both the *Sierra Leone Annual Medical Report* and the *West African Medical Journal*. In 1930 a fuller account was published in Leitch's *Dietetics in Warm Climates*, and also in pamphlet form, which was announced in this journal. The later work contains the statements that the earliest and most reliable sign of human A-avitaminosis is a characteristic alteration—glazing—of the surface of the tongue. The angles of the mouth take on a white appearance, as "eczematous," and the texture of the skin of the limbs and trunk is frequently altered by a keratosis which causes it to be dry and rough. All these symptoms are the result of vitamin A deficiency, and heal rapidly on the exhibition of a vitamin A concentrate. Whilst discussing the diagnosis of this avitaminosis the typical cornification of the skin was considered an important early diagnostic point. It may be of interest to recall the significant observation that this condition was most easily studied in the pregnant woman. In fact, the whole complicated syndrome of this avitaminosis disease, which ends in disorders of the nervous system if not given dietetic treatment, was elucidated at the first ante-natal clinics in Sierra Leone in 1927. I have defined the A and B avitaminosis disease as "a disease distinct from pellagra and beri-beri, characterized by lesions of the mucous membranes and skin, especially evident at the mucocutaneous junctions, associated with or followed by disorders of the nervous system, and curable by the addition of cod-liver oil and yeast to the diet."

Dr. Goodwin's patient, a child aged 10 years, suffered from glazed tongue, moist eczema at the left angle of the mouth, keratinization of the skin, and inability to stand up for any length of time, and was cured by the administration of cod-liver oil and a liberal diet. It will be seen that there is a definite similarity between the A and B avitaminosis disease and Dr. Goodwin's case. It is interesting to note in this connexion that in 1930 Dr. H. S. Stannus, in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, expressed the opinion that the disease I described was the "pellagra fruste" of French writers.

The object of this letter is to draw attention to a syndrome definitely associated with A-avitaminosis, which, although being increasingly recognized in the Tropics, is apparently little known in England. In conclusion I should mention failure or dimness of vision as one of the most baffling symptoms in this disorder—one

most frequently found in school children and pregnant women, but fortunately easily curable if diagnosed in time.—I am, etc.,
Wembley, July 24th. E. J. WRIGHT, M.R.C.S., D.T.M.

Cyanide Poisoning: Rasputin's Death

SIR,—Regarding the recent correspondence on Rasputin and potassium cyanide, I should like to point out that this is a most unstable substance. It is usually a mixture of cyanide and cyanate—also carbonate. When exposed to air it deliquesces, smells of hydrocyanic acid and ammonia, the former being produced from the cyanide and the latter from the cyanate by the action of water:

It is therefore most probable Rasputin was given a mixture of potassium hydroxide and carbonate, neither of which is likely to cause immediate death, and not potassium cyanide at all.—I am, etc.,
Catford, S.E., July 28th.

F. P. WALTON, B.Sc.

Tuberculin

SIR,—Those who evolve the policy that determines the fate of the hundreds of thousands of victims of tuberculosis in the poorer classes should be ready to adopt any method of treatment that has been proved by logical method to be of real value. We must not bow to authorities whose reputations are at stake. Dr. Bardswell and Dr. J. D. Macfie must fight for their stereotyped ideas upon sanatorium treatment, even though this system can never greatly help the poor.

It is certainly true that for the moment artificial pneumothorax *et hoc genus omne* have given the sanatorium system a fresh lease of life. But even granting the value of surgical expedients in resting the areas heavily attacked by tubercle bacilli, so far as the industrial population is concerned sanatorium treatment and surgical expedients are both costly and limited in their scope. True statistics will prove that sanatorium treatment can never greatly help more than 10 per cent. of the sufferers in the industrial classes, while surgical measures cannot help even this proportion of sufferers. What becomes of the remaining 75 to 80 per cent. of victims? That is the phase of the problem which has always interested me. Neither Dr. Bardswell nor Dr. Macfie offers any solution to this aspect of the problem. My solution has never been studied seriously. Dr. Macfie tells us he has used it "extensively" by carrying about four or five different tuberculins to the dispensaries and sanatoria under his charge. What he did with these tuberculins we do not know. Has he produced any evidence on this ambulatory method? Certainly if Dr. Macfie followed Dr. Bardswell's system of using tuberculin he was doomed to fail.

Long ago I laid down the conditions upon which an investigation into the value of any method of treating tuberculosis by scientific or other methods should be based. After-examinations in five years are indispensable. Recently, in my book *Tuberculin, its Vindication by Technique*, I proved that in the specific treatment of tuberculous diseases of the eye, which can be controlled directly by naked-eye examinations, assisted by instruments, large doses were necessary—often both exotoxins and endotoxins—to ensure arrest of the disease for any length of time. Dr. Bardswell was afraid to use large doses, and he failed. I feel justified in concluding that Dr. J. D. Macfie also failed for similar reasons. I am bold enough to say that the evidence in my last book justifies me in asking for a commission of inquiry, com-

posed of men who can give a right value to evidence such as I have to give.—I am, etc..

W. CAMAC WILKINSON, M.D., F.R.C.P.

London, W.1, July 28th.

* This correspondence seems to have reached a stage at which it cannot profitably be continued.—Ed., B.M.J.

Traffic Control by Light Signals

SIR,—I could agree with Dr. W. W. King Brown (July 21st, p. 141) that a longer warning to stop than that given by the yellow light would not be necessary if one were not liable to prosecution for accidentally making a crossing after the yellow light has suddenly appeared ahead. One is entirely at the mercy of the opinion of the police officer who sees the incident. As regards his rather satirical remarks on the subject of control of the car, the word "control" can only be used relatively. No car doing 30 m.p.h. is under control if some unexpected object such as a dog or human being leaps in front of it. However, one must assume that your correspondent never drives at such high speeds! By the phrase "bring the car under control" I meant, of course, such degree of control that it can be stopped within a few feet without stamping on the brakes.

My remarks on the need for more warning to stop were intended particularly to apply to fast main roads such as the Great West Road. In the big towns, where traffic moves generally more slowly, the need for such preliminary warning is not great. Suffice it to say that large numbers of drivers have endorsed my view that more warning to stop than that given by the present amber light is not only desirable, but vitally necessary. If Dr. King Brown ever should misjudge a yellow light and be summoned for it, he may change his view!—I am, etc.,

London, S.E., July 21st. GUY BOUSFIELD, M.D. Lond.

Unemployment Assistance: Determination of Needs

SIR.—We understand that under the new Unemployment Act a very large number of the unemployed and their families will come to depend partly or entirely for their support upon the allowances granted by the Unemployment Assistance Board. Our experience as physiologists and members of the medical profession leads us to believe that there will be grave danger of widespread physical deterioration, especially among the growing generation, if a considerable section of the population, obliged for reasons beyond its control to depend for maintenance on public funds, is unable to purchase sufficient food and other necessities for healthy existence.

We therefore welcome the provision made in the Act that the allowance granted to an applicant "shall be determined by reference to his needs, including the needs of any members of the household . . . who are dependent upon him." The definition of "needs" is necessarily left to the Board to determine; it is stated, however, that it is the function of the Board to promote the welfare of the unemployed and "to provide for the re-establishment of such persons with a view to their being in all respects fit for entry or return to regular employment." We suggest that a standard of needs which will fulfil the intention of the Act can only properly be arrived at in consultation with medical and other expert opinion qualified to estimate the minimum requirements of healthy living and the cost of satisfying them for families of various sizes.

"Needs" are conveniently divided into: (1) food; (2) rent; (3) fuel; (4) clothing; (5) light, cleansing materials, and sundries. With regard to food, scientific knowledge has now reached the point where it is possible to determine fairly accurately the minimum necessary to maintain health and working capacity. The findings of the recent Joint Conference representative of the British Medical Association and the Ministry of Health Committees on Nutrition on the constituents of a physiologically desirable dietary, and the work of the B.M.A. Committee on specimen minimum diets, can no doubt be used as a basis for estimating the minimum expenditure necessary.

With regard to other needs further investigation might have to be undertaken before a satisfactory standardization could be agreed upon. An adequate expenditure on food will only be secured if some margin is allowed for the small conventional necessities of civilized life. A scientifically determined scale such as we have in mind would obviously have to be adjusted to changes in the cost of living from place to place and from time to time.—We are, etc.,

Obituary

THE LATE MR. CHARLES HEATH

Mr. H. NORMAN BARNETT (Bath) writes: Charles Heath was the man who first attacked the stronghold of the old-fashioned so-called radical mastoid operation. His method of doing so may not have been always wise, but it is open to question, if he had pursued gentle flank movements instead of direct assault, if he would have been listened to, or if the citadel would have fallen as it undoubtedly has to-day, giving place to the conservative procedure in this region of surgery. To Heath is due, originally, the honour of having shown that mastoid disease may be cured without the destruction of the hearing apparatus of the middle ear, and his position in this regard should be very fully realized and appreciated. One side of Heath's character that does not seem to have been generally appreciated is that he was really shy, and was often hurt by the lack of sympathetic understanding shown to him. As an example of this I may state that he went to the International Congress at Copenhagen with a manuscript prepared to submit to that Congress, but he was so obsessed by the likelihood of the lack of an appreciative hearing that he came straight back to London without having spoken. There is arising a new generation of aural surgeons who imagine that conservatism in dealing with mastoid disease has been evolved in their own fertile brains, while there is at least one Central European otologist who has had the temerity to label a proceeding exactly similar to Heath's with his own name. Charles Heath received no titular distinction, although one was offered to him in connexion with his work on hygienic footwear for the soldier. This he refused, though he would have welcomed such recognition of his scientific work as an otologist. A great man has passed away from the ranks of aural surgeons, and it is only fitting that we should recognize and acknowledge the importance of his work.

Mr. WILLIAM FOSTER CROSS, who died on July 14th, was born in 1873, within the precincts of St. Bartholomew's Hospital, of which his father, William Henry Cross, was Clerk for nearly forty years. He naturally received his medical education at that famous school, and obtained the diplomas M.R.C.S., L.R.C.P. in 1896.

OBITUARY

[THE BRITISH
MEDICAL JOURNAL]

After a year as house-physician at Bart's he went as resident medical officer to the Tottenham Hospital. By this time his interest in anaesthetics was already marked, and by persevering work and thoughtful inquiry he built up for himself a high reputation both as an administrator of anaesthetics and as a teacher. After a long period as resident anaesthetist at Bart's he was appointed a member of the visiting staff of the hospital, in succession to Edgar Willett in 1905, and became senior administrator of anaesthetics on the resignation of Richard Gill in 1916. Many a student learned first from him the wisdom of anaesthesia as well as the value of the bold measures, and he added much to the value of the discussions in the Section of Anaesthetics of the Royal Society of Medicine. A man of kindly and attractive personality, he will long be remembered with affection by former colleagues and pupils. Many an anecdote of his training survives to recall his strongly held opinions, as well as his readiness to accept new advances when these had proved themselves. After many years of loyal and devoted service to St. Bartholomew's Hospital, he retired with the well-earned distinction of being appointed consulting anaesthetist. He had latterly been living near Falmouth, and his death at the relatively early age of 61 is widely regretted. Mr. Cross was president of the Abernethian Society in 1895, and took the chair at its centenary meeting, held on May 1st of that year, when Sir James Paget was present and Sir Norman Moore gave an address.

Dr. DANIEL JOHN FRANCIS O'FLANAGAN, who died on July 16th at his residence in Gower Street, London, after a long illness, was a man of broad sympathies and wide experience as a general practitioner. Born in Sacramento, he was educated in California and at Dublin University. In 1919 he obtained the diplomas L.R.C.P.I., L.R.C.S.I., and the L.M. of the Rotunda Hospital. He held appointments as house-surgeon at the North Ormesby Hospital at Middlesbrough, the Grimsby and District Hospital, and the Burton-on-Trent General Infirmary. He then started general practice at Middlesbrough, and became greatly esteemed, holding various posts in connexion with assurance companies, as well as being medical officer and public vaccinator to two districts and on the staff of the Middlesbrough Public Assistance Committee. Three years ago Dr. O'Flanagan decided to remove to London, where he had already begun to build up a large and successful practice. Increasing illness, however, handicapped his work, despite his active nature, and his death at the age of 46 removes a keen-witted and able practitioner who had made for himself a wide circle of friends. He was interred at St. Pancras Catholic Cemetery on July 19th. He had been a member of the British Medical Association since qualification.

The death took place at Newbury on July 16th of Dr. FREDERICK DITTMAR, who, until the beginning of the present year, was Medical Inspector in the Department of Health for Scotland. Dr. Dittmar graduated M.A. at Glasgow University in 1889, and M.B., C.M. in 1893, proceeding to his M.D. with commendation in 1896. After a period of study in Vienna, he became medical officer of health at Scarborough, and later took up the post of assistant M.O.H. for Glasgow, and assistant medical officer in H.M. Prison, Glasgow. Shortly afterwards he was appointed Medical Officer to the Local Government Board, and when the functions of that Board were widened, he became successively Medical Officer to the Scottish Board of Health and to the Department of Health for Scotland. Dr. Dittmar took the Cambridge D.P.H. in 1901, and in 1914 he joined the Royal College of Physicians of Edinburgh as a member, becoming a Fellow in 1918. He was the author of numerous works dealing with public health subjects, including *Report of Meat Inspection (1907)*; *Incidence of Enteric Fever in Scottish Burghs over 20,000 Inhabitants (1911)*; *Administrative Control of Pulmonary Tuberculosis in Glasgow*, which was published in collaboration with Drs. T. F. Dewar and E. M. McVail; and *Administrative Treatment of Undefined Cases Certified as Scarlet Fever*, published in collaboration with Dr. J.

Brownlee in 1897. In 1922, with Dr. Gerald Leighton, he investigated the celebrated epidemic of food poisoning at Loch Maree, in which, for the first time in Scotland, he identified the *B. botulinus* as the cause of the deaths.

With the death of Dr. GILBERT HENDERSON GRIFFITHS of Deganwy on July 13th there passed one who was held in high esteem and general affection as a general practitioner. Born in 1867, he was a medical student in Liverpool, obtaining in 1891 the diplomas M.R.C.S., L.R.C.P. After holding the posts of resident medical officer to the Parish Infirmary, Liverpool, and house-surgeon to the Wallasey Dispensary, Liverpool, and general-practitioner to the mouth of the Conway, then a small hamlet at the mouth of the Conway, his practice steadily increased as the local community grew in size, and many a Welsh and English family learned to rely on his skill and welcome his friendship. Dr. Griffiths's interests were wide. He was a keen tennis player, and enjoyed other forms of sports. He was a zealous Freemason, rendered loyal service to his Church, and was a strong Conservative. On the day of his death he was seeing patients in the morning, and a sudden heart attack in the evening brought his life to a close. He had been a member of the British Medical Association since 1897. He leaves a widow, a daughter, and a son.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The E. G. Fearnside Scholarship, value £100, for the encouragement of clinical research in organic diseases of the nervous system, has been awarded to John Bishop Hamman, M.A., B.Chir., F.R.C.S., of St. John's College.

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

M.D.—Branch I (Medicine): H. G. Anderson, W. E. K. Coles, T. A. Ll. Davies, S. N. Evans, A. Garland, J. C. Heather, L. H. Howells, K. D. Keele, A. Kennedy, F. P. L. Lander, L. G. Norman (University Medal), *E. Renbourn, T. S. Stone, F. W. Ta'Bois, M. R. Thomas, F. W. Willway, A. L. Wingfield, Branch II (Pathology): Dorothy Woodman, Branch IV (Midwifery and Diseases of Women): Marion J. Cunnning, K. M. Masani, Branch V (Hygiene): R. C. Cohen, D. D. Payne, G. E. B. Payne. ACADEMIC POST-GRADUATE DIPLOMA IN MEDICAL RADIOLOGY:—W. M. Hewetson, P. Hogan, S. R. G. Pimm, A. M. Vlok. *Awarded a mark of distinction.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

ACADEMIC POST-GRADUATE DIPLOMA IN BACTERIOLOGY.—Mary C. Baker, D. N. Chakravarti, S. C. Ghosal, G. P. Gladstone, V. Glass, P. P. Grigg, Betty C. Hobbs, G. W. Rea, F. C. Storrs.

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL

The following scholarships have been awarded: *Entrance Science Scholarships*: First, J. A. S. Green (Clifton College); second, C. B. B. Downman (City of London School); *Entrance Scholarship in Arts*: J. P. Irwin (Stonyhurst College).

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

A quarterly meeting of the Royal College of Physicians of Edinburgh was held on July 17th, with the President, Dr. Edwin Bramwell, in the chair. Dr. David Rhys Lewis (Swansea) was introduced, and took his seat as a Fellow of the College. Dr. John Ronald Currie (Glasgow) and Dr. Alastair Graham Cruickshank (Edinburgh) were elected Fellows.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College, held on July 25th, Dr. A. H. H. Sinclair, President, was in the chair. The following, having passed the requisite examinations, were admitted Fellows:

G. H. Cashmore, J. R. Crumie, P. N. Cutner, H. L. N. Davies, A. Duff, R. W. Graham-Campbell, B. R. Hallows, R. A. H. Krynauw, C. C. McKellar, N. Pencharz, G. W. Pottinger, S. C. Sinha, C. F. Sullivan, A. Track, D. C. Trainor, A. van der Poel, A. Watt, R. Withers, A. G. Young.

ROYAL AUSTRALASIAN COLLEGE OF SURGEONS

The eighth annual general meeting of the College will be held in Melbourne, beginning on March 4th, 1935. On that afternoon the building of the College will be declared open by the President of the Royal College of Surgeons of England, Sir Holburt Waring. In the evening, at the Wilson Hall, University of Melbourne, the third George Adlington Syme Oration will be delivered by Professor F. Wood-Jones. During the remaining part of the week operative demonstrations will be given at the Melbourne, Alfred, St. Vincent's, and Children's Hospitals. Surgical papers will be delivered by Dr. D. C. Balfour of the Mayo Clinic, Dr. Dean Lewis of Johns Hopkins Hospital, Professor C. F. Saint of Capetown, Sir D'Arcy Power of London, and Sir William I. de Courcy Wheeler.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At the quarterly meeting of the Council, held on July 24th in the College House, with the President, Dr. J. S. Fairbairn, in the chair, Dr. Fairbairn was re-elected President, and Dr. H. Russell Andrews and Dr. Bethel Solomons were elected Vice-Presidents. The following officers were also re-elected: honorary treasurer, Mr. Eardley Holand; honorary secretary, Professor W. Fletcher Shaw; honorary appeal treasurer, Sir Comyns Berkeley; honorary librarian, Dr. A. E. Giles; honorary assistant librarian, Mr. F. Roques. Miss Louisa Martindale, M.D., B.S., F.C.O.G., was co-opted a member of Council.

The following were elected members of the College:

Nicholas Attygalle (Ceylon), John Nicholas Chesterman (Sydney), Arthur Frederick Clift (London), T. F. Corkill (New Zealand), David William Currie (Leeds), Morgan David Arwyn Evans (Cardiff), William Dawson Galloway (Helmfrith), Frieda Ruth Heirhway (Sydney), Russell Norfolk Howard (Melbourne), Robert James Kellar (Edinburgh), Marjorie Jean Lyon (Sydney), John Harold Peel (London), Jack Polonsky (South Africa), Arthur Lloyd Potter (Liverpool), John Lekan Scholes (Melbourne), Percy Norman Leonard Seager (Dublin), Nora Proctor-Sims (India), Thomas Francis Todd (Preston), Rufus Clifford Thomas (Porthcawl), Charles Henry Walsh (Liverpool), Charles Alexander Whitfield (Aldershot), Bryan Williams (London), James Smith Young (Glasgow).

The following were formally admitted by the President to the Fellowship of the College: Andrew Moynihan Clave (Leeds), John Ellison (London); and to the Membership: Charles Granville Chapman (Grimsby), Calvett Martin Gwillim (London), Gladys Hill (London).

The following were admitted in *absentia*: *Foundation Fellows*, H. C. E. Donovan (Melbourne), Edward Rowden White (Melbourne); *Foundation Member*, William Irving (New Zealand); *Member*, Agnes Marshall Cowan (Manchuria).

The draft scheme for an investigation into analgesics suitable for use by midwives was passed, and instructions given that arrangements should be made for the immediate initiation of the investigation.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—F. G. S. Alderson, G. W. Bender, J. T. Boocock, J. A. McClintock, A. J. McGuire, H. J. Ripka, F. W. Treadwell.
MIDWIFERY.—F. G. S. Alderson, J. A. Amor, S. M. Sabat.
FORENSIC MEDICINE.—T. D. R. Aubrey, J. W. D. Bull, W. C. Campbell, D. S. G. Genge, S. Klein, J. E. T. Mann, S. M. Sabat.
MIDWIFERY.—T. D. R. Aubrey, J. W. D. Bull, G. W. Bender, C. C. Jounides, S. J. Navin, J. C. Paterson, J. F. L. Walley.

The diploma of the Society has been granted to G. W. Bender, S. Klein, A. J. McGuire, and H. J. Ripka.

CONJOINT BOARD IN SCOTLAND

The following candidates have been approved at the examination indicated:

FINAL PROFESSIONAL EXAMINATION.—Ida Hirschmann, S. Hertz, Eleonore Bergmann, J. Plesch, E. Zuckermann, H. Kober, E. Lucas, S. K. Westmann, E. Jacobsohn, C. H. Rothschild, C. C. Becker, M. Gutstein, H. Feld, W. Auerbach, W. Kupfermann, I. K. Leshnansky, F. J. Newhall, R. Samson, P. Kahn, P. Nathan, E. Marx, Martha Turk, A. Lechner, O. Hartog, Sally Rammelsburg, A. Mann, E. Gostynski, M. S. Khan, F. Ewer, J. L. S. Strelow, P. Perlman, A. S. W. Buchanan, R. H. Hunt, C. W. A. de Silva, H. Jannemann, R. Hamburger, Nathalie Rothschild, Jessie R. Bruce, H. A. Thorner, J. F. Macgregor, L. C. Goldwater, H. Fleming, P. T. Hauff, F. A. Paul, L. H. Becker.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Parliament is now in recess until October 30th, when the House of Lords and House of Commons will reassemble.

In the House of Lords, on July 25th, the Road Traffic Bill was read the third time. On July 26th the House of Commons approved, after discussion, all the amendments made by the House of Lords to the Bill. The Royal Assent was given on July 31st.

On July 24th the Shops Bill was returned to the House of Lords from the House of Commons, with amendments agreed to. The Bill received the Royal Assent on July 25th. Other Bills receiving the Royal Assent were the Ministry of Health Provisional Order Confirmation (South Middlesex and Richmond Joint Hospital District) Bill, and the Ministry of Health Provisional Order Confirmation (Weymouth and Portland Joint Hospital District) Bill on July 25th, and the Milk Bill and the Poor Law (Scotland) Bill on July 31st.

In the House of Commons on July 26th the return of licences showing the number of experiments on living animals performed during 1933, which was ordered by the House on June 20th, was presented.

The Parliamentary Medical Committee met on July 25th and reviewed the work of the session.

Importance of Town Planning

In the House of Commons, on July 26th, on the vote for the Ministry of Health, Sir PERCY HARRIS opened a discussion on town planning. Sir FRANCIS FREMANTLE said that houses were growing up, generally, in a way that was a disgrace to the present age. Housing was going on at a great pace, and the pace would be increased, especially in the areas that wanted planning more than anything else—that was in the case of areas of slum clearance and overcrowding. Town planning required to come first and housing afterwards. Planning was sticking unnecessarily. In planning there was very great difficulty in visualizing the future. Sir Francis asked the Minister whether there was not now an opportunity for him to advise local authorities that it was in their power to plan only superficially and provisionally for the most part where areas were still purely rural, and to leave it open for a supplementary scheme to be introduced at a later date. He believed it was possible to work the Town Planning Act in that spirit, putting emphasis on the fact that they must lay down their plan in advance for the main development, and for the minor development to be left over for the time being. It was essential to plan for the immense movement of population. About 100,000 persons were being moved out of London every year, and were settling down in different areas round London. So far as possible that movement should be associated with the re-siting of factories. The movement of factories must be allowed, largely, to decide itself, and the planning of housing and the other requirements of civilization ought to be around the factory, which should be the nucleus. We had made a mistake in trying to see where residences should go and letting factories take their own line.

Sir HILTON YOUNG said that at present, when housing was advancing at a rate unexampled in the past, and when the towns were spreading so rapidly into the country, there was special requirement for greater foresight and attention to our planning activities. Sir Francis Fremantle had produced the impression, perhaps unintentionally, that town planning was sticking. He cordially agreed that the rate of progress, both of the organization of the work and of its actual achievement, was not all that could be desired, but the House ought not to receive the impression that no advance was being made. Ten years ago the number of authorities engaged in the active preparation of schemes was 218; to-day it was 803. In ten years the number of acres covered by town-planning schemes had increased from 1,200,000 to 12,000,000. To increase the efficiency of planning work it was necessary to rationalize and widen the executive areas over which planning could be

administered. For that reason the Government's policy had always been directed towards the promotion of regional planning committees, wherever they were required and could be instituted. Wisdom and progress would be obtained by promoting reasonable co-operation between local authorities, and not by arbitrarily overriding them. It was an encouraging figure for the future that in ten years we had increased the number of executive committees that actually controlled the work from one to seventy-five. The discussion closed.

Bathing Pools and Diphtheria
